<b>13. ABSTRACT (Maximum 200 words)</b>  Pilot vehicle interface (PVI) testing usually requires extensive human-in-the-loop (HITL) simulation. An alternative to HITL testing is to model human computer interaction with an automated cognitive engineering tool. This study used Soar cognitive modeling to compare the effectiveness of an existing and proposed PVI for air-to-ground Maverick missile missions. The baseline interface used a Forward-Looking Infrared Radar (FLIR) to detect and designate targets. The improved PVI had an enhanced FLIR and added Real-Time Information in the Cockpit (RTIC) with annotated overhead imagery of the target area. The Soar software architecture was chosen to model pilot cognition, although target acquisition was more dependent on the pilot's visual and motor functions than cognition. The Soar model accurately predicated faster target acquisition for the RTIC PVI and faster target acquisition for reduced scene complexity. Although not statistically significant, the Soar model correctly indicated that increased scene complexity caused larger increases in target acquisition time for the RTIC PVI condition as compared to the baseline condition (HITL 179% increase, Soar 47% increase). Furthermore, Soar was the only model that accurately predicted increased latency in the RTIC condition while both Cognitive and Traditional Task Analyses predicted decreased latencies.

## ABSTRACT

Automated testing is an engineering tool used to test designs by exposing them to a variety of conditions and combination of conditions in an efficient manner. While guidelines exist for designing *human computer interfaces (HCIs)* or in the special case of aviation, the *pilot vehicle interface (PVI)*, testing these interfaces usually requires extensive *human-in-the-loop (HITL)* testing. An alternative to HITL testing is to model human computer interaction in software and employ the model as an automated cognitive engineering tool for testing HCI/PVI design for the purpose of understanding the impacts on human performance and mission effectiveness.

The present study used computer simulation to compare the effectiveness of an existing and proposed PVI for air-to-ground strike missions employing the Maverick missile. The baseline interface involved using *Forward-Looking Infrared Radar (FLIR)* to detect and designate targets. The improved PVI enhanced FLIR contrast and added *Real-Time Information in the Cockpit (RTIC)* overhead imagery of the target area with targets marked. These PVIs had been previously tested by HITL simulations and several software models. Keeping this effort blind to the results of the previous efforts, the Air Force only provided task analyses and measures used in the earlier efforts so comparisons could be made.

The Soar software architecture was chosen to model pilot cognition because of its human-like cognitive capabilities. As it turned out, target acquisition for this particular mission scenario was more dependent on the parameters chosen for the pilot's visual and motor functions than cognitive processing. However, the Soar results presented here were comparable to HITL data and the other cognitive modeling simulations. Even though the visual and motor parameters chosen for the Soar model had limited correlation to the HITL data, the Soar model did accurately predict faster target acquisition for the RTIC PVI and faster target acquisition for sparser scene density. Although not statistically significant, the Soar model correctly indicated that increased scene complexity would have a greater increase on target acquisition for the RTIC PVI condition as compared to the baseline condition (HITL 179% increase, Soar 47% increase). However, the previous models failed to indicate the increased target acquisi-

tion times for increased scene complexity for the RTIC condition when compared to the baseline condition (***Cognitive Task Analysis (CTA)*** 105% decrease, ***Traditional Task Analysis (TTA)*** 124% decrease).

## **ACKNOWLEDGMENTS**

Completion of this project would not have been possible without the cooperation of several individuals. Mr. David Hoagland, an engineer at the Air Force Research Laboratory, provided management assistance through the ***Crew-Centered Cockpit Design Technology (CCDT)*** Program Office. Mr. Tom Hughes of Veda Inc., provided data from the previously run simulations for comparison. Ms. Holly Bautsch of Logicon Technical Services provided valuable insights and a partial copy of her Masters thesis which was based on some of the previously run simulations. Dr. John Laird of the University of Michigan provided suggestions about Soar, its operations, and how it could be manipulated to create cognitive behaviors during an air-to-ground strike mission.

**SYTRONICS'** President, Barry Myers, encouraged this project as it was coincident with his company goal of creating leading-edge research. We would also like to thank all the other **SYTRONICS** employees who assisted in this work; Vince Schmidt and Brian Cooper for their technical assistance and Becky Rogers and Debbie Winner for assistance in preparing this document.

This work was done for the Air Force using a contractual agreement with the CCDT under a U.S. Army Research Laboratory Federated Laboratory Cooperative Agreement DAAL01-96-2-0003. We wish to express our appreciation to Mr. Bernie Corona, Agreement Manager, who made this work possible through the Army fiscal instrument.

## INTRODUCTION

A growing number of accidents and incidents can be directly or indirectly attributed to mental errors made by human system operators (O'Hare, Wiggins, Batt, and Morrison, 1994). These errors are particularly disturbing to the engineers who build these systems because the hardware and software all worked as intended, but the result was still tragic failure. Clearly, there is a pressing need to be able to predict the circumstances leading to and ultimately diminishing the possibility of such mental errors. One approach to predicting such errors is to perform high-fidelity, HITL simulations and observe where cognitive breakdowns appear. Unfortunately, there are drawbacks to this approach which make thorough testing impractical. The combination of high-fidelity simulation costs, limits in skilled operator availability, behavior differences between simulation and real flying, and the limitless combinations of events capable of triggering cataclysmic accidents make thorough HITL testing impractical.

An alternative approach to HITL testing is to model the operator's cognitive performance, subject the model to the broadest range of possible circumstances, and record where the cognitive failures occur. This is analogous to automated testing which is already extensively used by engineers to increase product reliability. Although modeling human cognition is a fledgling science, modeling methods do exist, such as ACT\* and Soar, which can serve as the basis for automated testing. Cognitive automated testing of user interfaces has both advantages and disadvantages. On the down side, automated cognitive testing lacks the face validity of HITL and the quality of the outcome is dependent on the quality and scope of the model. However, such testing can investigate large numbers of circumstances, especially unusual circumstances, at a lower cost and in less time. Furthermore, models can be readily changed and adapted as additional information and test runs become available. This kind of modeling could be used to predict which unusual circumstances cause these low frequency mental errors. Cognitive modeling could become a primary tool for designing and evaluating user interfaces, and potentially decrease the occurrence of metal errors.

## Architecture Selection

Marshak, Pohlenz (now Wesler), and Smith (1996) considered how cognitive modeling could be employed in the crewstation design process and speculated on how best to implement such a model for Armstrong Laboratory's CCDT Program. A survey covered the existing cognitive modeling literature and identified the bases for a predictive aircrew cognitive model. The literature revealed two leading candidates in which to implement the cognitive model. The first is Anderson's ACT\* (1983) architecture (current version ACT-R) which grew out of cognitive psychological theory; and Laird, Rosenblum, and Newell's (1985) State, Operator, and Result (Soar) architecture based on an artificial intelligence architecture which mimics human performance. The following explanation borrows heavily from Marshak, et al. (1996).

Anderson's (1983) ACT\* model for cognition tries to provide a comprehensive explanation for high-level cognitive control behavior. There are three distinct memory structures in Anderson's model: working, declarative, and production. **Working memory (WM)** holds relevant information from declarative memory, sensory inputs, and the actions of productions (explained in the following). **Declarative memory (DM)** contains a tangled hierarchy of information clusters, each with no more than five elements. **Production memory (PM)** contains IF-THEN condition-action pairs with conditions drawn from DM and actions inserted in WM.

Anderson's theory is based on empirical findings of human learning and memory studies and as such, has been elaborated to match the theoretic thinking in that domain. This introduces elaborations as separating memories into temporal, spatial, and abstract classes. ACT\* offers six kinds of interactions in WM and five different mechanisms for conflict resolution. Although these theoretic elaborations match the complexity of human cognitive processing theory, they also increase parameterization and allow multiple predictions based on which combinations of processes are operating.

A somewhat simpler human cognitive modeling scheme was proposed by Card, Morgan, and Newell (1983). The **Model Human Processor (MHP)** was a general model for human problem-solving. MHP postulated three interacting subsystems (perceptual, motor, and cognitive) each with their own processor and memories. Per-

ceptual stores include visual and auditory memories. Motor stores have the ability to store sequences of motor behaviors. Cognitive stores include working and long-term memory. Operation of the MHP model is based on the Recognize-Act cycle, where productions are drawn from long-term memory into WM and the results of their firing modifying WM. Operations are governed by the principles of discrimination (retrieval based on uniqueness), uncertainty (decision processes slow with uncertainty), and rationality (goal-orientation).

The MHP model has evolved into what is now called Soar. Soar is an advanced expert system software architecture which employs a decision engine modeled after human problem-solving. However, Newell (1990,1992) asserts that Soar is a candidate for a unified theory of human cognition instead of being just another computational expert system. Newell supports his claim based on a common mental chronometry (similarities in timing), a common architecture with perception and motor function, and a convergence of Soar's behavior with data on human operations and learning. Newell eloquently supports the relationship between Soar and human cognition by pointing out Soar can predict or explain many human learning and memory phenomenon.

Under Newell's urging, Soar incorporated human intelligence strategies as part of its software architecture. The first feature added was universal sub-goaling as a means of overcoming impasses. If Soar cannot initially achieve a solution to a problem, it defines more attainable sub-goals which are attainable. Once these sub-goals are attained, the final goal is tested again and if not yet achieved, new sub-goals are defined. This process continues until the ultimate goal can be attained from the last achieved sub-goal. Universal sub-goaling circumnavigates impasses without arbitrary assumptions or ineffective trial-and-error processes.

Another important feature of Soar is the use of chunking as a learning process during problem-solving. Chunking, the phenomenon reported by Miller (1959) that overcomes the limitations of short-term or WM, allows combination of IF-THEN production rules into related groups. The chunking hypothesis is that "A human acquires and organizes knowledge of the environment by forming and storing expressions, called chunks, which are structured collections of the chunks existing at the time of learning"

(pg. 142; Rosenbloom in Laird, Rosenbloom, and Newell, 1986). It uses a stimulus-response relationship between contents of chunks and follows from human learning theory. Chunking enables Soar to manage the complexity of large production rule bases by organizing them into chunks of increasing complexity. Rosenbloom goes on to show how Soar behavior seems to mimic human performance on memory and problem-solving tasks.

The Soar approach has certain advantages that favored its application in simulations over ACT-R. First, Soar is an extremely parsimonious approach to cognitive modeling; lower model complexity means a more deterministic approach. Perhaps even more important is that Soar is already being employed in modeling aircrew behaviors. The **Defense Advanced Research Project Agency (DARPA)** funded both Drs. Laird and Rosenbloom to develop **intelligent forces (IFORs)** for the **Synthetic Theater of War (STOW)** combat simulation. The Soar architecture had already been ported into the **Modular Semi-Automated Forces (ModSAF)** software system. ModSAF provides aircraft flight dynamics and weapons models while Soar provides the intelligence to “fly” IFOR aircraft autonomously. By using Soar, this substantial existing DARPA effort could be leveraged to create a working model with a minimum of time and effort. Another advantage to the Soar-ModSAF approach is that it is **distributed interactive simulation (DIS)** compatible. Models developed using Soar-ModSAF could be tested in complex DIS scenarios and improvements made by cognitive modeling could enhance Soar performance in STOW.

### Background

The CCDT Program had already conducted a HITL simulation and created two different models to predict the effectiveness of cockpit display and control changes in the F-15 based fighter and its ability to deliver multiple Maverick missiles during a single attack run. The baseline configuration consisted of a F-16 cockpit simulation using the **Low Altitude Night Targeting and Infrared Navigation (LANTIRN)** targeting pod to deliver two fire-and-forget Maverick air-to-surface missiles. The LANTIRN pod provides a wide 6° and a narrow 1.69° field-of-view display through which the pilot must detect, identify, and designate the target vehicles. Targets were KC-10 tankers parked among

multiple (2 or 4) B-52 bombers on an airfield's ramps and taxiways. In a typical LAN-TIRN attack, the pilot will fly at medium altitude (7500 feet or 2286 meters) and air-speed (480 knots or 247 m/s) directly toward the target. The LANTIRN targeting pod FLIR display is used to view the target area and to designate targets for Maverick launch. When the target is within the Maverick's optimum range, the pilot fires one or more weapons at the designated targets.

The second configuration evaluated by the CCDT Program is an enhanced cockpit which was also HITL simulated and modeled. The enhanced cockpit contained two significant improvements. First, the RTIC provided a satellite view of the attack area with all targets marked. Second, the FLIR was improved to provide 30% better contrast than the baseline FLIR image. It was anticipated that the advanced knowledge of the target location coupled with the improved LANTIRN FLIR contrast would reduce the target acquisition time and increase target designation accuracy.

The CCDT Program had already developed two other models of the baseline and enhanced configurations which were created to determine how well the models predicted the HITL simulation performance. One model was built using the ***Extended Air Defense Simulation (EADSIM)*** while the other was developed using MicroSaint™ modeling software. The CCDT Program wished to compare the Soar model with all three of the previous efforts. Thus, the present modeling effort was informed only of the dependent measures used in the other simulations and was otherwise kept "in the blind" to the results of the HITL, EADSIM, and MicroSaint™ simulations so that a fair comparison could be made. The performance of the other simulations was provided only after the Soar simulation was created and data collection runs were complete.

One problem identified early on about using Soar to model the CCDT Maverick launch mission is that this particular mission is very sequential in nature. Hence, the mission was not particularly mentally challenging and could not utilize the advanced cognitive modeling features of Soar, i.e., sub-goaling and chunking. The mission outcome is largely based on perception rather than cognition and calls for a modeling approach more suited to discrete event simulations rather than Soar's cognitive approach. Hence, the bulk of the results reflect the ability to predict the perceptual tasks. Under-

standing this lack of stress on Soar's capability, approval to build a Soar model of the Maverick launch mission was granted. The goal was to determine whether Soar could be used to micro-model pilot behaviors (STOW programming is at a tactical level), perceptual input, and motor output processes. This limited effort could be followed by a more comprehensive one which modified the mission with more cognitively-taxing characteristics which would completely test Soar's ability to cognitively model pilots with the hopes of developing a cognitive engineering tool for automatic testing of mentally-demanding, human computer interfaces.

## SIMULATION DESIGN AND METHODS

### Summary of Requirements

#### Mission

The ground attack mission begins with the pilot and vehicle at an altitude of 7500 feet, flying at a speed of 480 knots, and heading east toward the first waypoint, waypoint one. As indicated in Figure 1, the pilot then turns 90 degrees left and heads due North to the IP point and then continues due North to the target area where the pilot will designate, lock, and fire two Maverick missiles at two KC-10 aircraft on the ground (there are also four to eight B-52 aircraft on the ground and in the proximity of the KC-10s which serve as distractors). The starting point is at least 5.1km from waypoint one and waypoint one is 5.1km from the IP. All reported times are relative to the time the pilot reaches the IP point. All reported distances are relative to the target or target area.

The pilot knows there are four possible plane groupings for each trial, but only two of the four groupings will be populated in a given trial. The pilot knows that in each of the populated groups there will be only one target aircraft, a KC-10. Hence, once the pilot has identified and designated the KC-10 in the first group, the pilot can assume all the remaining, yet to be identified aircraft for that group are B-52s. Thus, the pilot will not identify the remaining aircraft in that group and the pilot can switch its attention to the second group. If the pilot miss identifies the KC-10 as a B-52 and identifies all the planes in a grouping as B-52s, then the pilot, knowing there must be one KC-10 in

the group, will "look" again at each plane until one plane is identified as a KC-10. After the pilot designates the second aircraft, the pilot switches to locking each of the Mavericks. The pilot then watches the range icon until the range is less than 58,000 feet. When the range is less than 58,000 feet, the pilot then pushes the fire button.

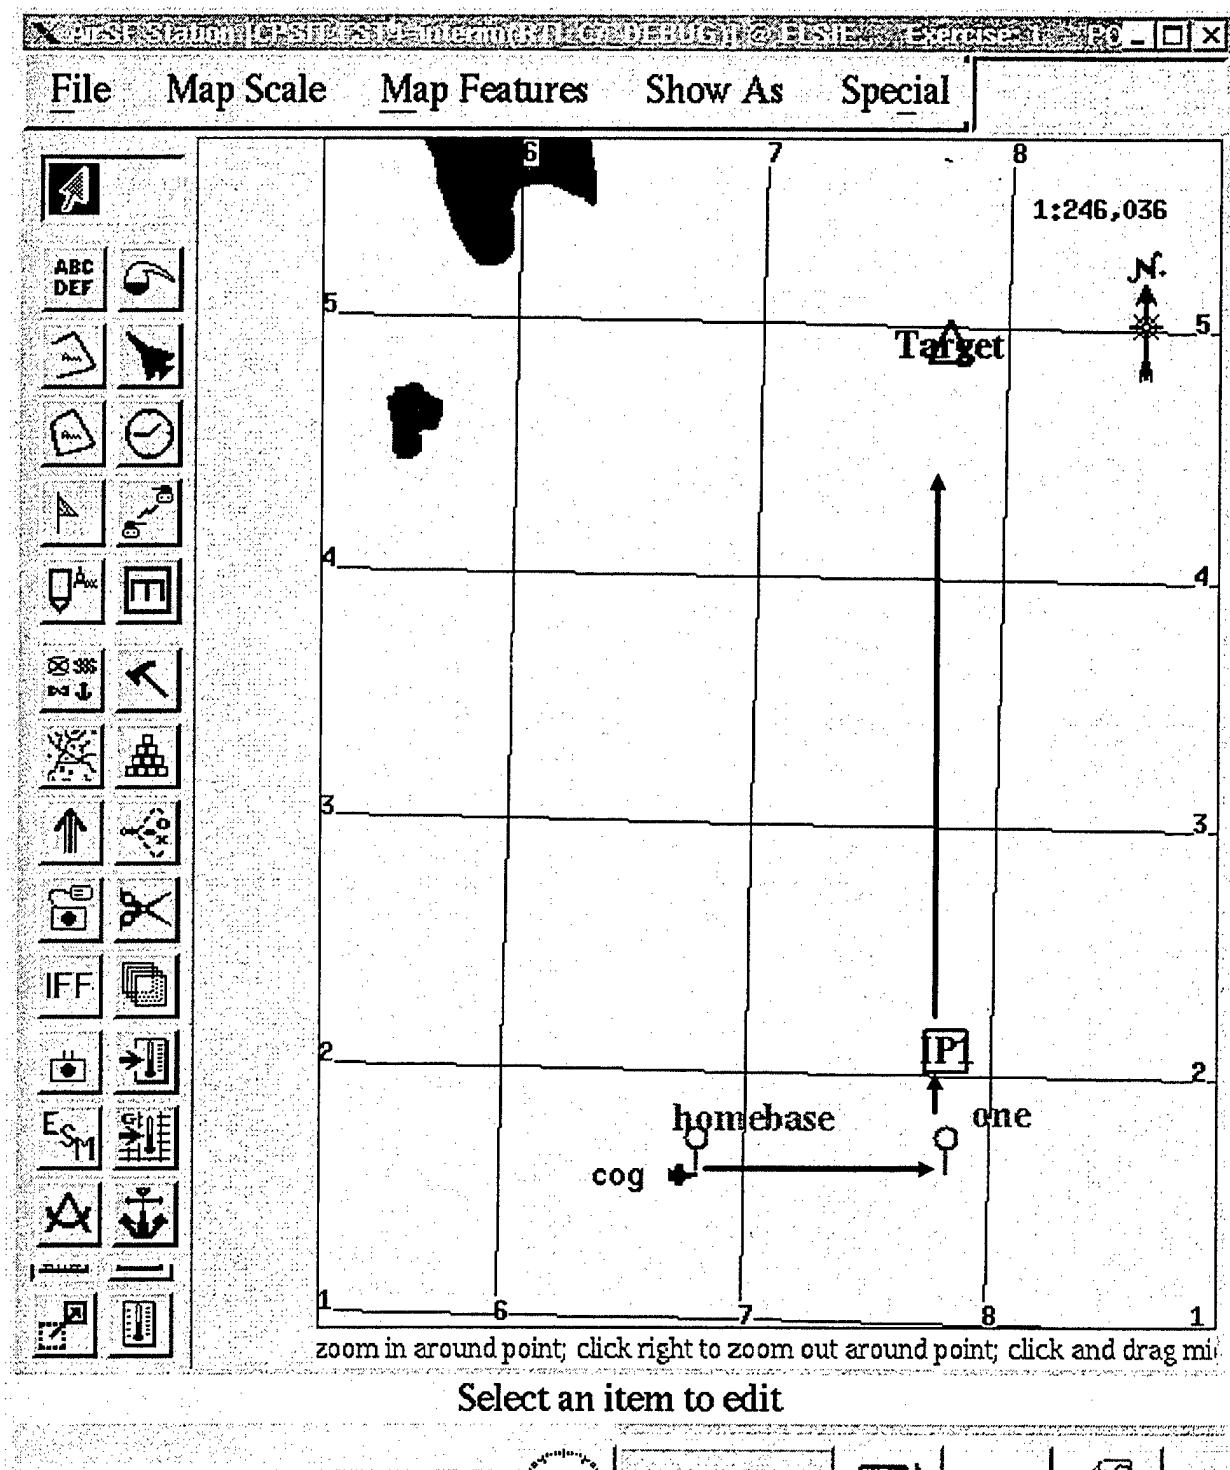

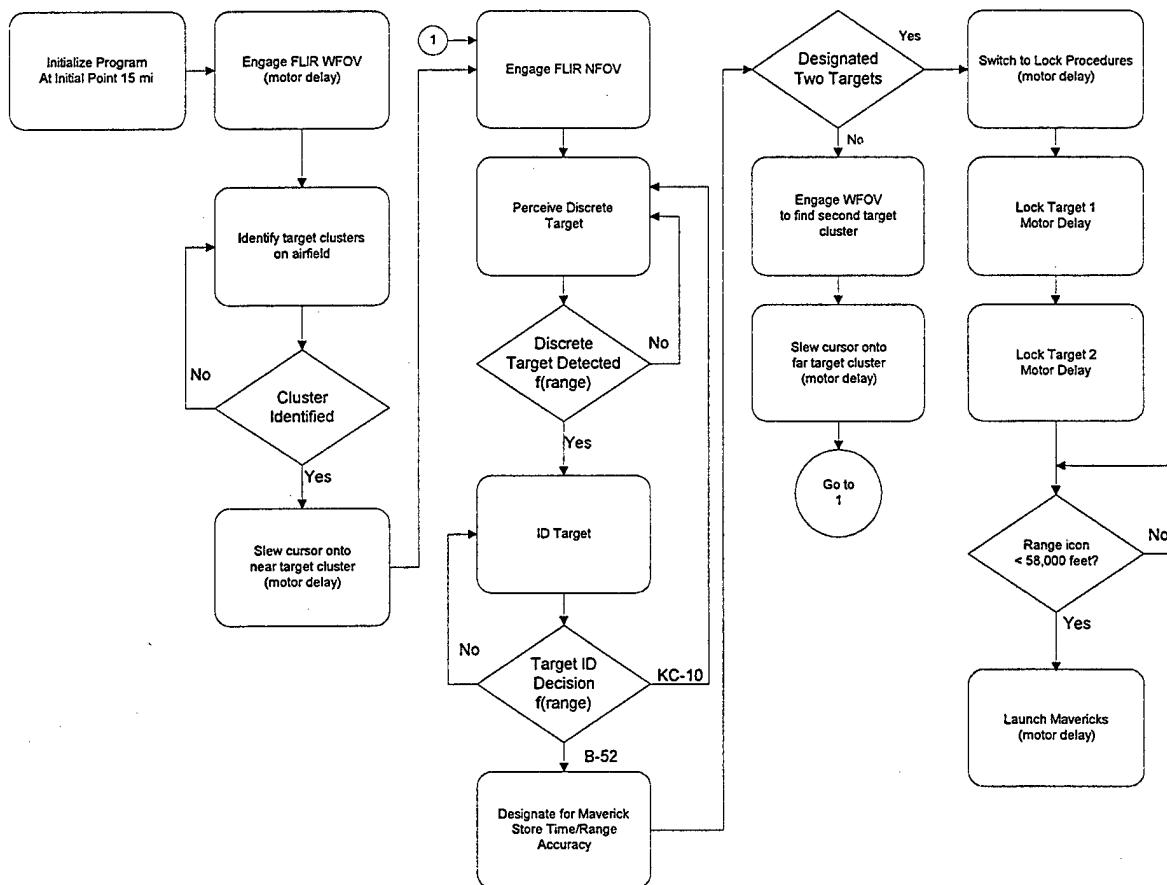

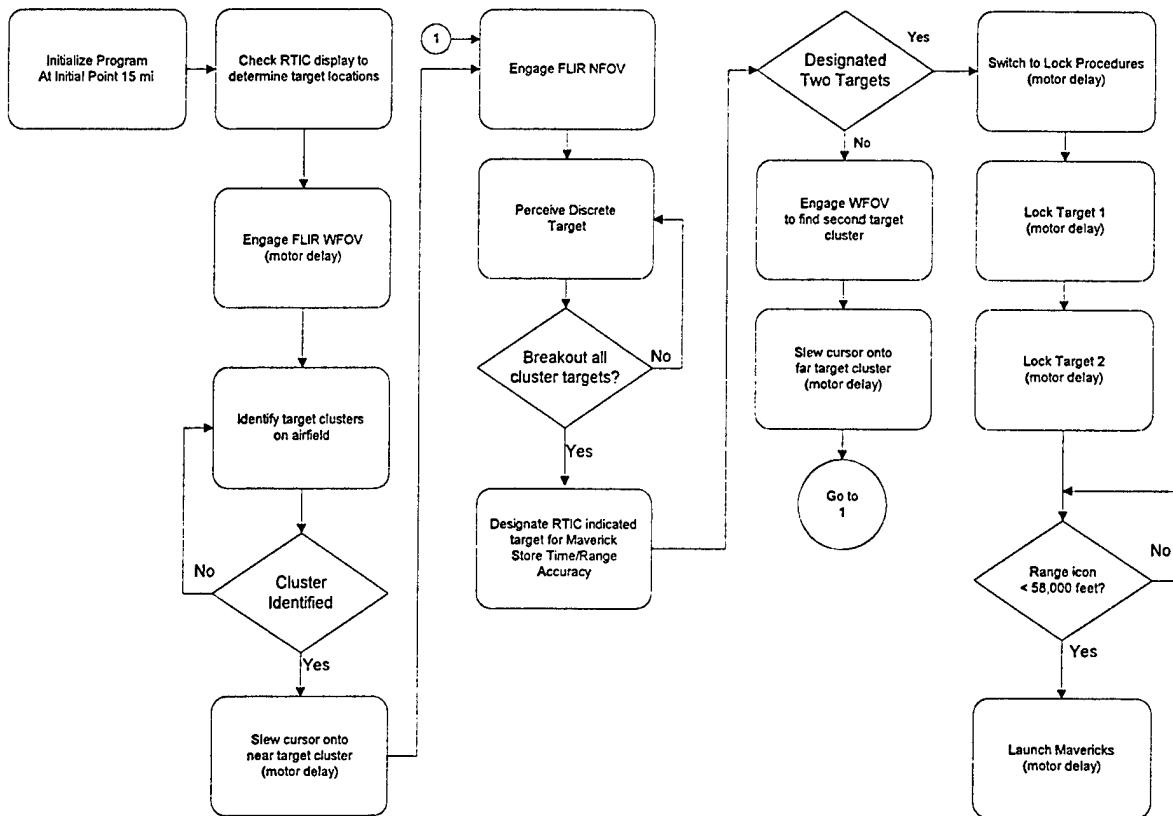

Figure 1. ModSAF Aerial View of Ground Attack Mission.

The behavior sequence is detailed graphically in Figures 2 and 3 and textually in the Appendix 1.3 and 1.4. Basically, there are two separate scenarios. The baseline scenario requires the pilot to detect a cluster of objects, then visually detect and identify each of these objects until a KC-10 is identified. After each instance that the pilot claims to detect a KC-10, the pilot designates that aircraft. After the pilot designates two aircraft, the pilot then switches to locking each of the Mavericks. Finally, the pilot watches the range icon and when the pilot is within 58,000 feet, the pilot pushes the fire button.

**Figure 2. Flowchart of Baseline Behaviors.**

**Figure 3. Flowchart of RTIC Behaviors.**

In the second scenario, the RTIC condition, the pilot is given a satellite view of the aircraft on the ground and the target aircraft, i.e., the KC-10 is highlighted. The solution to representing this graphical intelligence information was to calculate the centroid for each group and then to calculate the polar position of each aircraft in the group relative to the centroid. The target was then the aircraft that matches the relative angle and distance to the group's centroid. Hence, after detecting all the planes in the first group, the pilot designates the plane that matches this intelligence information. After the pilot detects all of the planes in the second group, the pilot designates the plane that matches that intelligence information. After the pilot has designated two aircraft, the pilot then switches to locking each of the Mavericks. Finally, the pilot watches the range icon and when the pilot was within 58,000 feet, the pilot pushed the fire button.

After the pilot pushed the fire button, the program recorded the trial number, the number of hits, misses, false alarms, and correct rejections. The program also records the time elapsed since the IP point and the range to the target and range to the pseudo airfield for the following parameters:

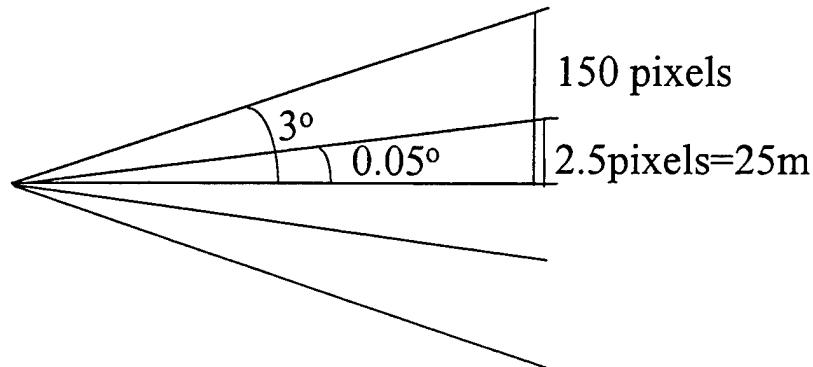

- First detection
- First identification (0 for the RTIC scenario)
- First and second designation
- First and second Maverick lock
- Launch

### **Soar Behavior Design**

#### Visual Model

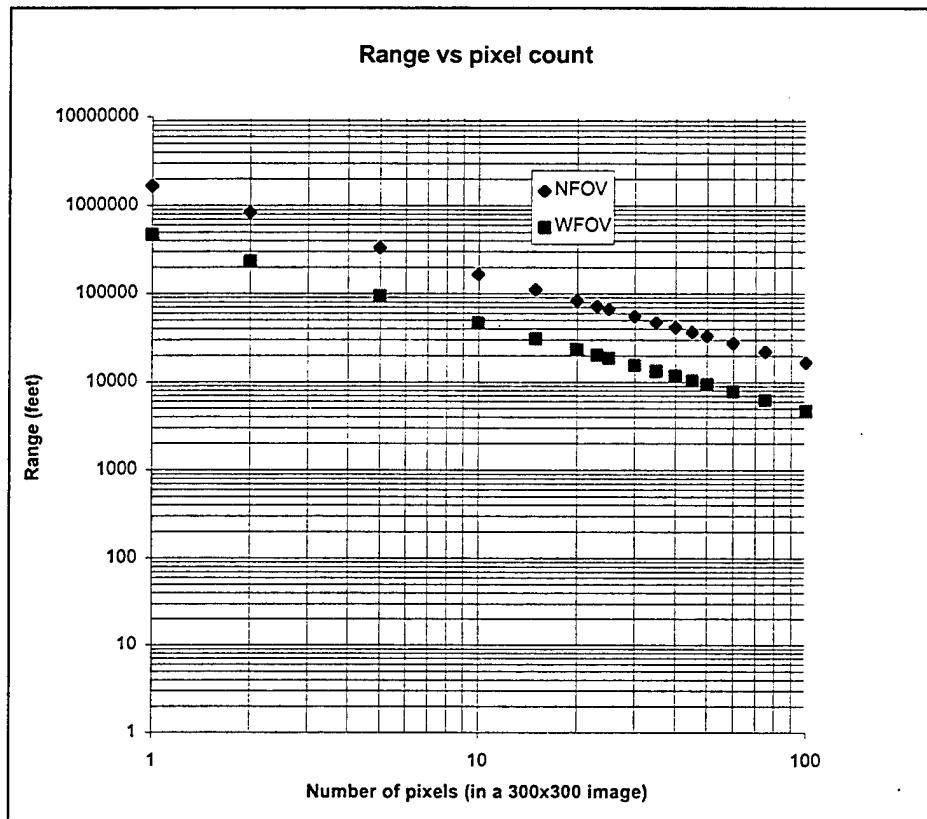

The existing Soar visual model had a range of seven nautical miles with perfect visibility, i.e., at distance of 7.001 nautical miles, the Soar pilot had no information about an object. However, at 6.999 nautical miles, the Soar pilot knew all it could about the object: lateral range, slant range altitude, heading, speed, location, call-sign, and vehicle type. To simulate WFOV and NFOV characteristics, the existing Soar behaviors were enhanced. First, the Soar visual lateral-range was increased to 32,000 meters (104,918 feet). After an aircraft was detected, the object was then assigned a detection slant-range and an identification slant-range. The detection range assigned was designed to have an average value of about 28.6 km with a standard deviation of about 1.0 km. The distance of 28.6 km was chosen because at this range, both the KC-10 and B-52 would subtend about five pixels on a 300x300 pixel screen of a 6.0° WFOV sensor as indicated by Equation 1 and Figure 4.

$$\sin\theta = \text{opp}/\text{hyp} \text{ or } \sin(0.05^\circ) = 25\text{m}/28.6\text{km} \text{ EQ .1}$$

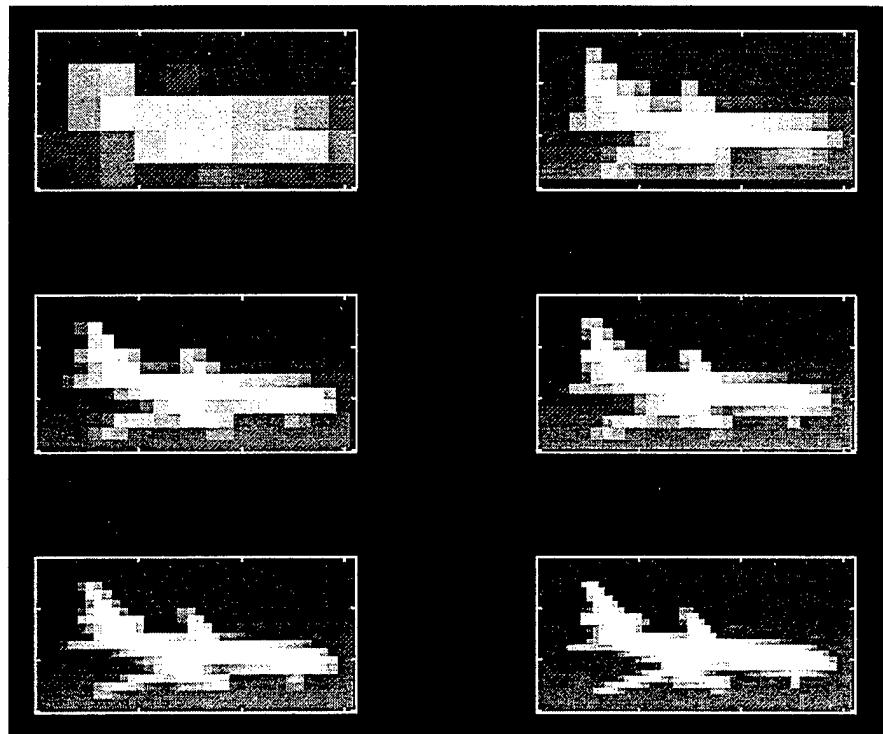

**Figure 4. Diagram of WFOV Angels and Pixels Used to Calculate Slant-Range Detection Limit.**

Determining the range at which a pilot could discriminate between a KC-10 and a B-52 required human subject data. Image pixelation was calculated based on aircraft size and range. The pixel subtense is plotted in Figure 5.

**Figure 5. Estimation of an Aircraft's Length in Pixels vs Range for WFOV and NFOV FLIRs. The angles used were 6.0 and 1.69 degrees for WFOV and NFOV sensors respectively. The aircraft were estimated to have a 163 foot wingspan.**

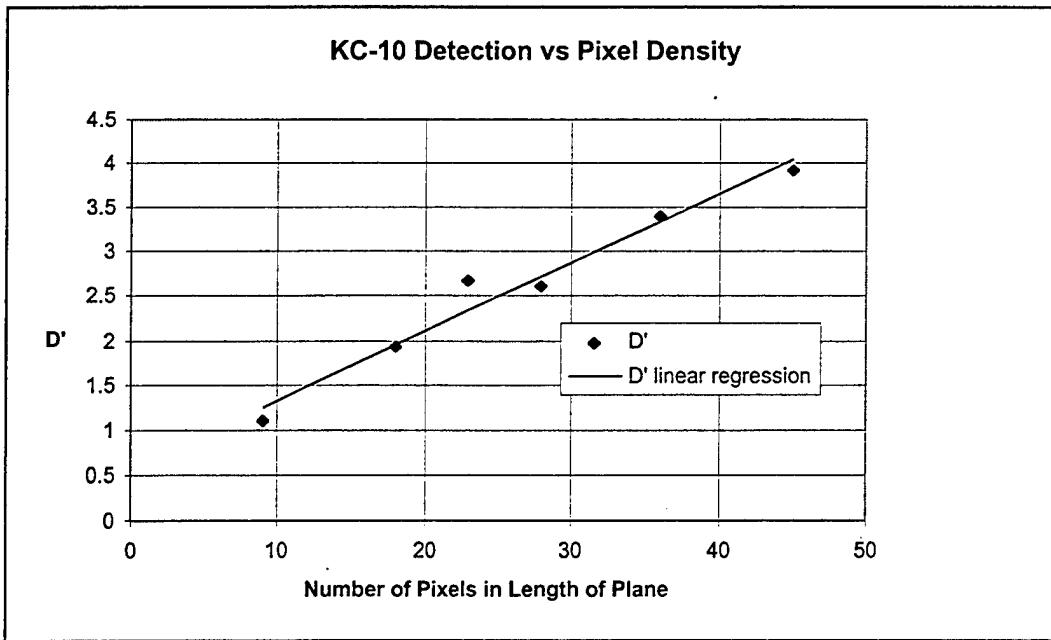

These calculations were the basis for creating pictures with the Image Processing Toolbox of Matlab (Thompson and Shure, 1995); an example of the output is shown in Figure 6. Human subjects were asked to identify pixelated reproductions of KC-10s and B-52s viewed from 15° angle above the horizon to approximate the medium altitude approach.

**Figure 6. One Recognition Test Plate for KC-10 Viewed 60° Off-Axis from the Nose View.**

See Appendix 1.2 for a complete set of B-52 and KC-10 pixelated images.

As seen in Figure 7, D' did not reach the 90% level until the plane subtended 25 pixels. The NFOV sensor has a 1.69° field-of-view. Thus, the minimum identification range can be calculated similarly to the WFOV calculations for detection range. The identification range is  $20.3 \text{ km} = 25\text{m}/\sin(1.69^\circ) \times 25/300/2$ .

**Figure 7. Ability of Novice Human Subjects to Discrimination Between KC-10s and B-52s Based Upon Pixel Density.**

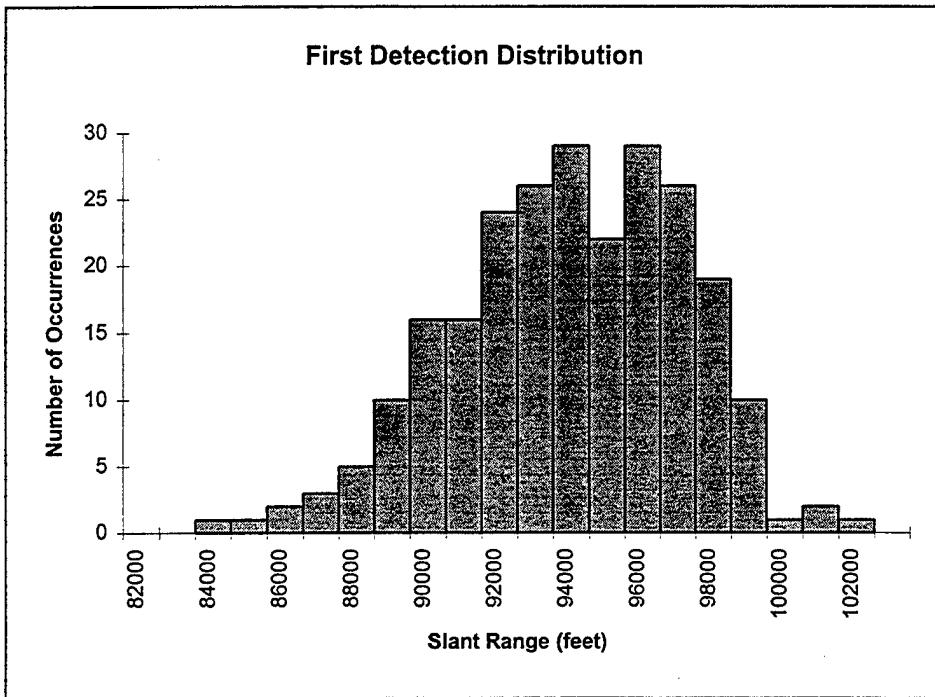

Thus, in the baseline scenario, the Soar pilot models discrimination between KC-10 and B-52 aircraft by the ability to see 25 pixels of the aircraft's length. However, an image subtending 25 pixels did not give the Soar model perfect vision. Behaviors were added so that at a displayed image of 25 pixels or slant range of 20 km, the pilot had a 90% chance of correctly discriminating between a KC-10 and a B-52. To model human behavior, the identification accuracy was dependent upon distance according to the following equations

$$P_{\text{identification}} = 0 \quad \text{Slant Range} > 96,000 \text{ feet} \quad \text{EQ . 2}$$

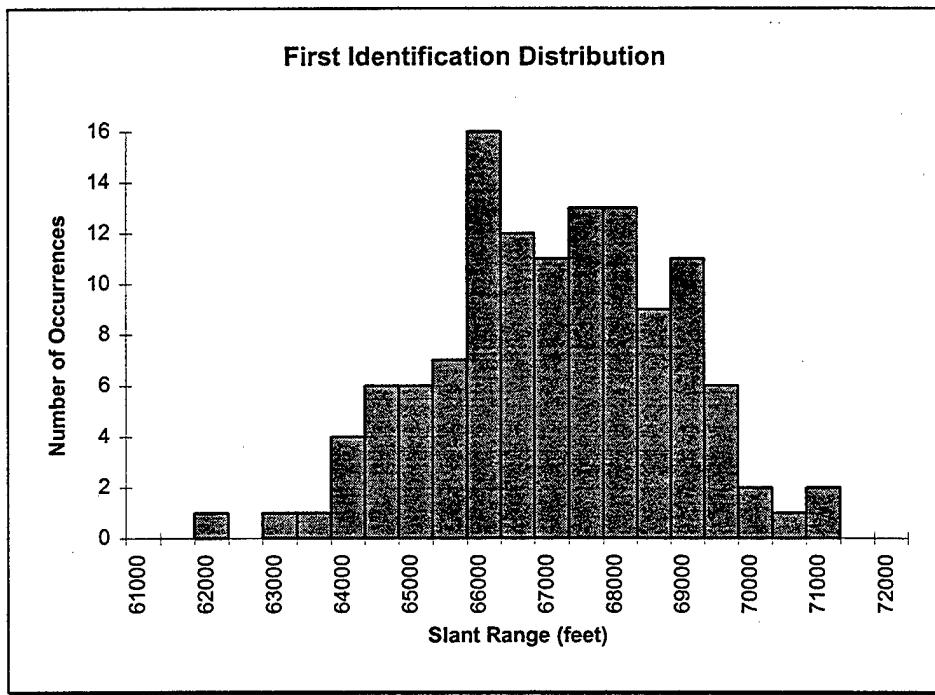

$$P_{\text{identification}} = 2.93 - 3.045E-5 * \text{range} \quad 96,000 < \text{Slant Range} > 63,000 \text{ feet} \quad \text{EQ . 3}$$

$$P_{\text{identification}} = 1 \quad \text{Slant Range} > 63,000 \text{ feet} \quad \text{EQ . 4}$$

As seen in Figures 8 and 9, identification distance had an element of chance associated with both the RTIC and baseline behaviors.

**Figure 8. First Detection Distribution for RTIC Condition.**

**Figure 9. First Identification Distribution for the Baseline Condition.**

In the RTIC scenario, the pilot did not need to visually discriminate between the KC-10 and the B-52. The pilot only needed to determine where the group of planes were, match the NFOV sensor image of the planes to the intelligence image, and then recognize the relative position of the target plane relative to the other planes in the group and then designate this same plane in the NFOV sensor image.

The solution to representing this graphical intelligence information was to calculate the centroid for each group of aircraft. Then, the polar position of each aircraft relative to the centroid was calculated. The target was then the aircraft that was both within 20 meters and 0.1 radians of the calculated distance between the centroid and KC-10 given in the intelligence information. Since the target position changed twice and the number of distracters changed twice, this caused the location of the centroid to be changed four times which required four sets of intelligence information. This mapping between the Soar supplied data located in files r1.soar, r2.soar, r3.soar and r4.soar and the plane layout configurations are seen in Table 1.

**Table 1. The Associative Mapping Between Soar Supplied RTIC Information and Plane Layout Sourced at the ModSAF Parser**

FILE NAME	PLANES PER GROUP	TARGET POSITION	PLANE LAYOUT (Corresponding file sourced at ModSAF parser)
r1.soar	3	1	1 - 6
r2.soar	3	2	7 - 12
r3.soar	5	1	13 - 18
r4.soar	5	2	19 - 24

#### Motor Model

Since the Soar language does not have any inherent mechanism for generating delays, the top-state attribute current-time was used as a timer. The resolution of the current-time attribute was one second. Hence, a delay set for one second has a theoretical delay of greater than zero but less than or equal to one second. Behavioral motor delays were added to prevent immediate execution of behaviors where motor delays were required. A summary of motor delays and the value of the programmed delays are seen in Table 2.

**Table 2. Summary of Simulated Motor Activity and Corresponding Programmed Delay**

MOTOR ACTIVITY	PROGRAMMED MOTOR DELAY
Engage WFOV	1
Switch to NFOV	1
Decide Hit, Miss, FA or CR	1
Designation and Confirm	1
Switch from Designation to Locking	3
Locking and Confirm	1
Launch	2

#### Randomization

Since Soar does not have a random number generator, random numbers were generated by calculating the sine value for the current-time value. To obtain a distribution that was not flat and had similarities to a gaussian distribution, three random numbers were averaged. To calculate the detection and identification ranges for each plane, the average of three random numbers were subtracted from 0.5 and this difference was multiplied by the variance for that parameter. This result was then added to the expected mean for that parameter. As seen in Figure 8 and 9, the distribution of detection and identification ranges have a gaussian-like distribution.

After the Soar pilot is focused on a particular plane and the slant range is less than the calculated identification range for that plane, then the probability for accurately identifying the focused vehicle is calculated as seen in equations 2, 3, and 4. This calculation is based upon the slant-range between the Soar pilot and the aircraft in question and a randomly-generated number having a flat distribution. If the calculated probability was greater than the randomly-generated number, then a hit or correct rejection was recorded. If the calculated probability was less than the randomly-generated number, then a miss or false alarm was recorded.

#### Program Description

As seen in Figures 2 and 3 (Flowcharts for Baseline and RTIC Behaviors) and Appendices 1.3 and 1.4 (selected text outputs from execution of baseline and RTIC behaviors), the mission starts with the Soar pilot flying toward waypoint one. After

achieving waypoint one, the Soar pilot turns north and flies to the IP. After achieving the IP waypoint, a timer is started, the pilot continues North at an altitude of 7,500 feet and speed of 480 knots and engages the WFOV. After a cluster of objects is detected, the Soar pilot switches to NFOV. The pilot continues to focus on one object in the cluster until it is both detected as a plane and identified. After identification, the validity of the identification is calculated and recorded as a hit, miss, false alarm, or correct rejection. Once a KC-10 is believed to be identified, a hit or false alarm, then the object is designated and the second cluster is processed. If a miss occurs, then all of the identification information for that group is erased after all the planes are identified and the identification process is repeated until a hit or false alarm occurs. After two aircraft are designated, the pilot switches to the launch procedures. The launch procedures consist of locking and confirming both of the Mavericks. After locking both Mavericks, if the slant range is greater than 58,000 feet, then the pilot watches the range icon. After locking both Mavericks, if the slant range is less than 58,000 feet, the pilot presses the fire button.

The RTIC behavior scenario differs from the baseline behavior outlined above in the identification process. In the RTIC behaviors the planes are not identified. After the cluster is detected in WFOV and the pilot switches to NFOV, the pilot focuses on each target and calculates the polar coordinates for that plane. If the plane's polar coordinates are not within the limits input by the intelligence information, then a correct rejection is recorded and the pilot proceeds to focus on the next plane in the group.

If the plane's polar coordinates are within the limits input by the intelligence information, then a hit is recorded, the plane is designated and the pilot proceeds to the next group or to launch procedures if this was the second group.

## RESULTS

### Analysis of Soar Model

The experiment contained two major variables, scene density and pilot vehicle interface. The scene was further complicated in that only two of the four possible vehicle locations were occupied. A bird's eye view of the field arrangement is presented in Figure 10. This requirement resulted in six different possible groupings (1-2, 1-3, 1-4,

2-3, 2-4, 3-4). Furthermore, the location of the target vehicle, the KC-10, was also varied between two locations within each group. Hence, the experimental matrix was a  $2 \times 2 \times 6 \times 2$  which was repeated five times for a total of 240 trials. Table 3 summarizes these independent measures.

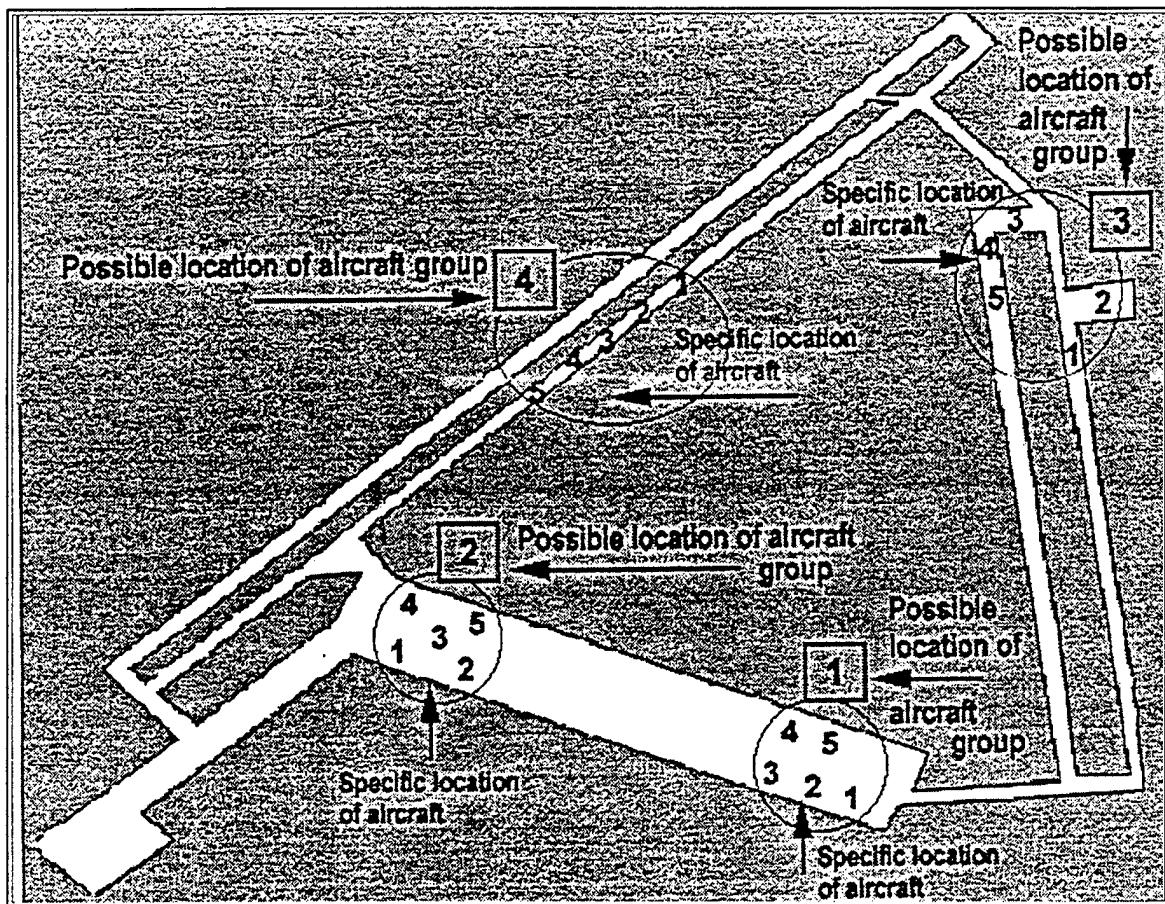

Figure 10. Airfield Area (from Holly Bautsch, 1997 pg. 27).

**Table 3. Arrangement of Independent Measures Used in Prior Efforts and by the Soar Model**

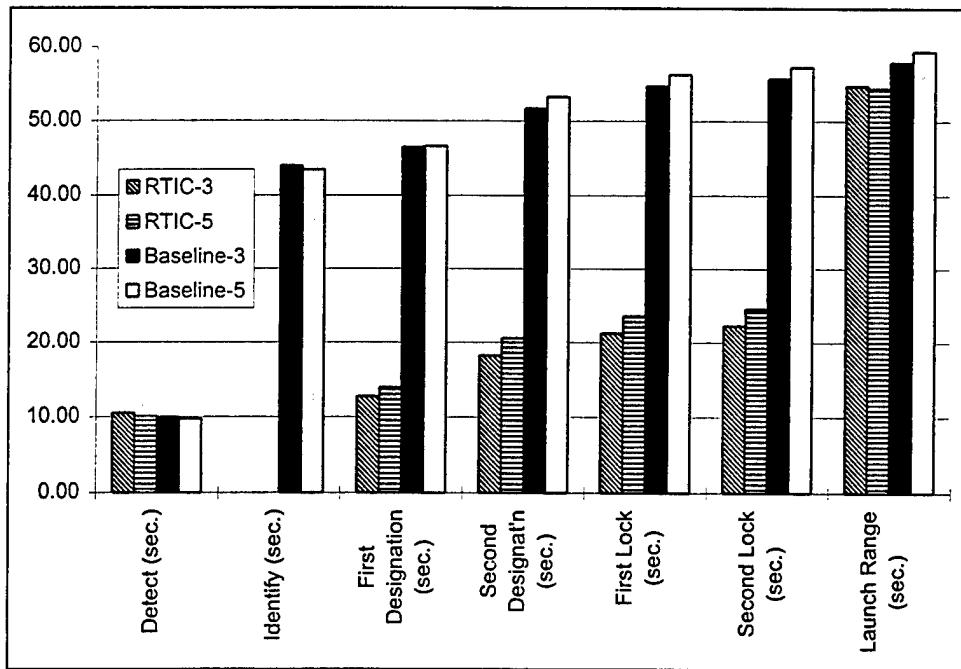

Variable	Levels	Variations
Pilot Vehicle Interface	2	Baseline Enhanced (RTIC)
Cluster Size	2	Three aircraft Five aircraft
Groupings	6	Two out of four possible airfield positions 1-2,1-3,1-4,2-3,2-4,3-4
Position in Cluster	2	Two positions used each in groups size three or five

The dependent variables measured included: detection time and range, identification time and range, designation time and range, lock time and range, launch time and range, and recognition accuracy. As seen in Figures 8 and 9, the modeling of detection and identification ranges did have a distribution that appears gaussian. The intended detection range average was 93,500 feet with a standard deviation of about 3,200 feet. The actual detection slant-range for all trials was 93,989 with a standard deviation of 3,247 feet. Similarly, the intended identification range average was 66,500 feet with a standard deviation of about 1,600 feet. The actual identification slant-range for all trials was 67,030 with a standard deviation of 1,729 feet.

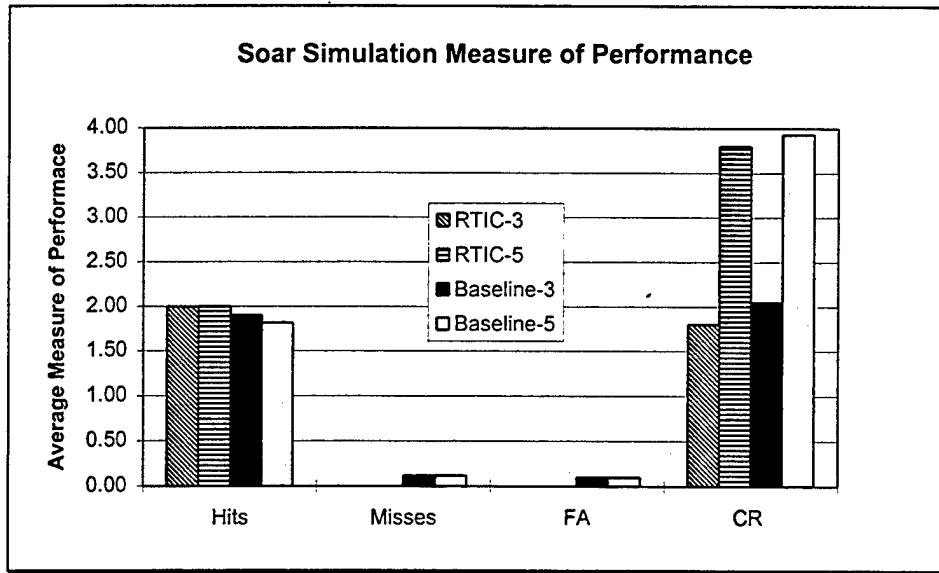

As expected from analysis of the visual model, the Soar-simulated RTIC interface resulted in significantly earlier designation and lock times compared to the baseline condition (first designation time:  $p=0.001$ ,  $F=3352$ ,  $N=60$ ; first lock time:  $p=0.0001$ ,  $F=3872$ ,  $N=60$ ). As seen in Figure 15, the first lock time for the RTIC condition with a scene complexity of three averaged only 21.25 seconds. The RTIC condition with a scene complexity of five was 2.2 seconds higher, due to the increased scene complexity. Conversely, the baseline condition with a scene complexity of three had an averaged first lock time of 54.72 seconds, 33.47 seconds longer than the RTIC condition. Similarly, scene complexity increased baseline first lock time by 1.58 seconds. Although the PVI and scene complexity interaction was not statistically significant, the increased effect for the RTIC condition should have resulted because in the RTIC condi-

tion, the Soar pilot must process each of the planes prior to identifying the target. However, in the baseline condition, the Soar pilot can terminate processing a group after the KC-10 is identified. Thus, in the baseline condition, the average number of vehicles expected to be processed with a scene complexity of three is two and with a scene complexity of five is three. Hence, increasing the scene complexity in the baseline condition will not increase the average lock time as much as the RTIC condition, but the variation should be much larger in the baseline condition. The variation in RTIC first lock times are about 4.5 seconds regardless of scene complexity. However, baseline lock time variation is 3.37 seconds for a scene complexity of three and increases to 4.04 seconds for a scene complexity of five. Although this time difference in variance is not significant ( $F=1.44$ ,  $N=60$ ), the difference in variance for first lock range for baseline condition between scene complexities is significant ( $F=1.88$ ,  $N=60$ ). The explanation for the significance is that the time has an increased variance due to the different times it takes to reach the same slant range from each group since the target groups are located at different distances from the IP.

Overall accuracy of performance was comparable for the four experimental conditions. Categories of responses for each condition are plotted in Figure 11. The most marked difference is the increased number of correct rejections when more B-52s appeared in target clusters.

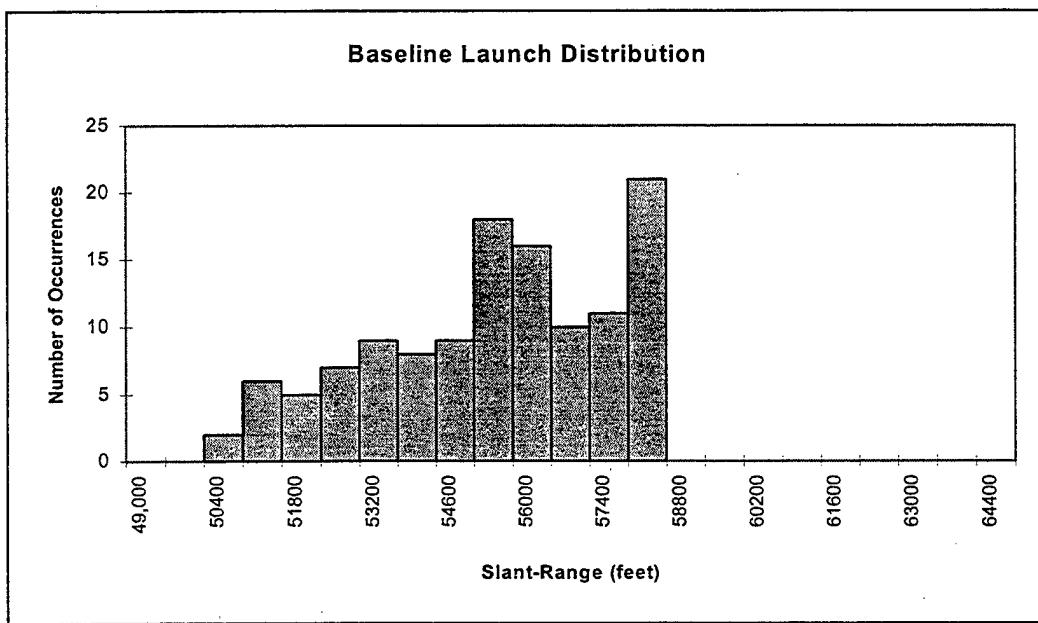

**Figure 11. Summary of Soar Simulation Times for Different Scene Complexities and Different PVIs.**

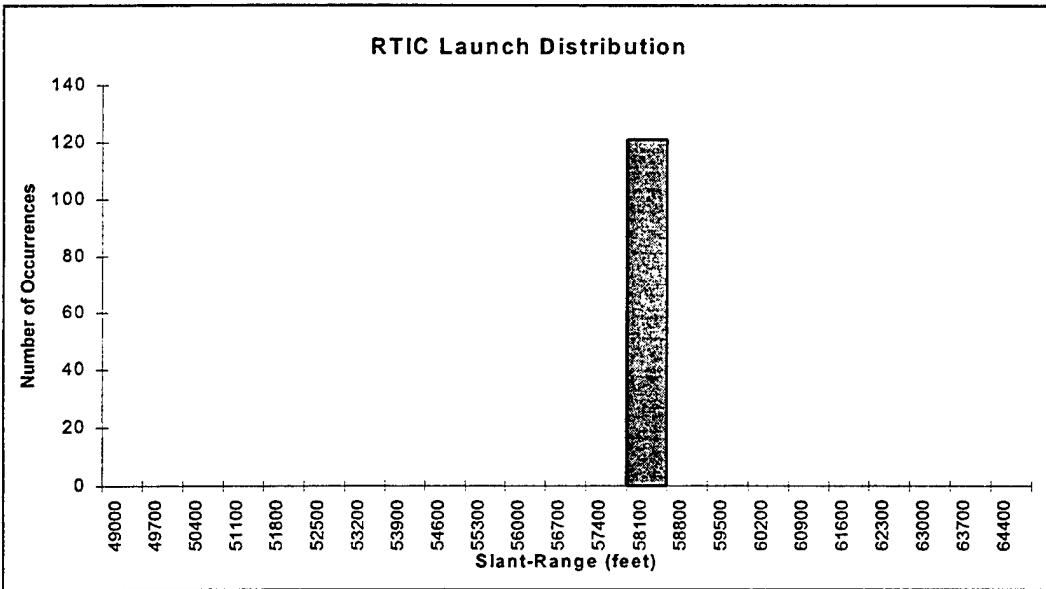

**Figure 12. Summary of Soar Simulation Performance Measurements for Different Scene Complexities and Different PVIs.**

The launch times between all conditions were very similar. The baseline behaviors typically resulted in the identification of targets and the locking of the Maverick missiles inside the maximum launch range. Hence, the baseline Soar pilot was typically

not waiting for the range icon to reach 58,000 feet. This resulted in a launch variation that was less than first lock variation due to clipping at the maximum launch range tail of the distribution as seen in Figure 12. Conversely, the variation in RTIC launch ranges was very small as seen in Figure 13 with range scales comparable to the baseline condition. This greatly reduced variation because in all the RTIC conditions, the Soar pilot was always watching the range icon waiting to pass the maximum firing range of 58,000 feet.

### Comparison of Soar Simulation Results to HITL, TTA, and CTA Simulations

After completion of the Soar simulation data collection process, data from HITL testing and other simulation models were compared to the Soar-simulated results. The results from HITL, Soar, *Traditional Task Analytic (TTA)*, and *Cognitive Task Analytic (CTA)* are summarized in Table 4. As seen in Figure 15, the Soar, TTA, and CTA simulations grossly under-estimated the first lock time for the baseline conditions, but Soar did surpass the TTA and CTA models in predicting RTIC first lock times. The Soar simulation over-estimated the first lock time in the sparser scene complexity indicating an under-estimation of the detection range in the visual model for the RTIC condition. In fact, close examination of the HITL data indicated that some pilots were locking targets prior to the IP point. Furthermore, Soar was similar to the other models in accurately indicating that additional distracters would increase the time required for a pilot to lock the missiles; although all simulations under-estimated the HITL data.

**Figure 15. Comparison of HITL First Lock Times to Soar, TTA, and CTA Base Simulations.**

**Table 4. Data Summary of Soar HITL, TTA, and CTA Data**

	SOAR			PIL (-32.98 seconds)			TTA (-32.98 seconds)			CTA (-32.98 seconds)		
	Pilot Vehicle Interface	RTIC	Baseline	RTIC	Baseline	RTIC	RTIC	Baseline	RTIC	RTIC	Baseline	
Scene Complexity	3	5	3	5	3	5	3	5	3	5	3

Detect (sec.)	10.53	10.10	9.97	9.78								
Identify (sec.)	0	0	44	43								
First Designation (sec.)	12.75	13.90	46.47	46.63								
Second Designation (sec.)	18.25	20.55	51.72	53.30								
First Lock (sec.)	21.25	23.55	54.72	56.30	15.95	24.02	27.40	30.42	27.55	27.72	51.99	
Second Lock (sec.)	22.25	24.55	55.73	57.30	26.92	39.93	44.70	49.37	35.19	35.17	61.94	
Launch Range (sec.)	54.78	54.43	57.93	59.42	40.77	53.28	58.28	62.27	40.23	40.02	67.19	
Launch Range (feet)	57894	57909	56147	54378	56845	46937	44552	42464	2912	29131	6132	
Hits (average)	2.00	2.00	1.90	1.82								
Misses (average)	0	0	0	0	0	0	0	0	0	0	0	
FA (average)	0	0	0	0	3	8	3	13	0	0	0	
CR (average)	1.80	3.80	2.05	3.93								

NOTE:

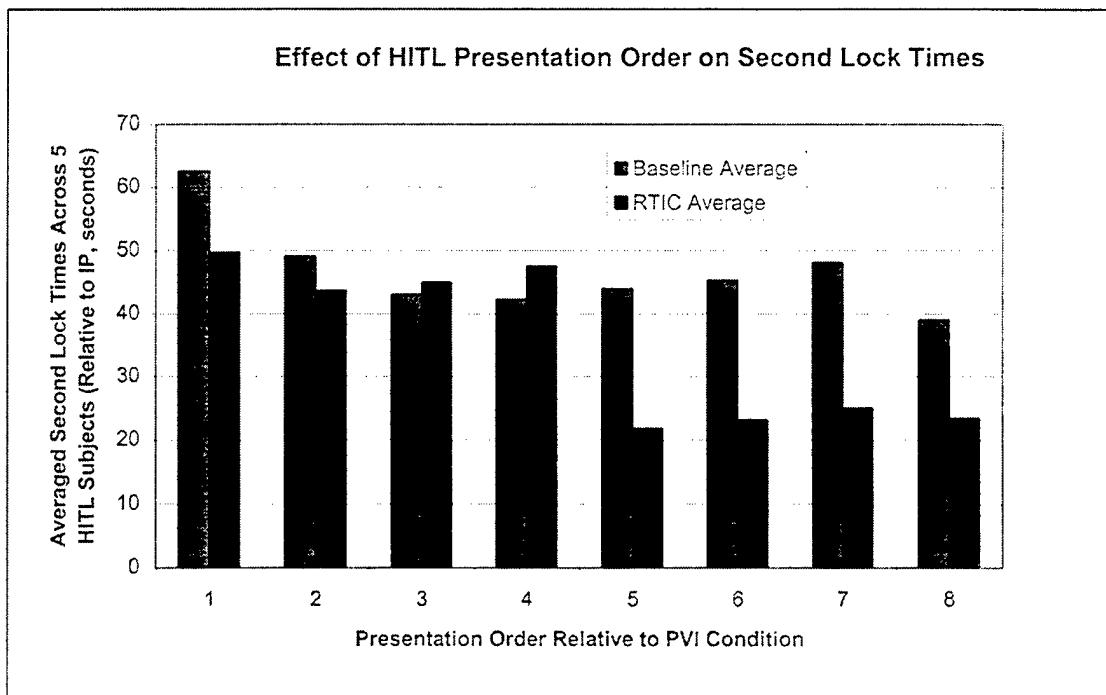

All times are expressed relative to IP. HITL, TTA, and CTA times were adjusted by using the average HITL time and range values from Holly Bautsch's thesis Tables 11 and 14 (32.98 seconds were subtracted from time values in order to make times relative to the IP).

Soar estimated the second lock time much better than the first as indicated in Figure 16. However, this improved estimate was due to the cancellation of a sluggish visual model and a hyperactive motor activity model. Given those limitations, one would expect that those differences would be canceled out when comparing PVIs of the same scene density. The HITL data indicated that for a scene complexity of three, the RTIC condition reduced the average second lock time by 17.78 seconds as compared to Soar, TTA, and CTA which reduced the averaged second lock time by 33.48, 26.75, and 14.76 respectively. This data is summarized in Table 5.

Careful analysis of the available HITL data shows an apparent confound. The presentation order to the human pilots appears not to be counter-balanced for presentation order with respect to scene complexity. Apparently, for a given PVI, a scene complexity of five was always given first and a scene complexity of three seconds. The HITL data for each subject was taken in four sets of four trials where the baseline and RTIC conditions were interwoven. The difference between sets for a given PVI is seen in Figure 17 as a step function between the fourth and fifth trials which corresponds to the end of the first set and beginning of the second set. Whether this difference is due to a learning effect in the RTIC condition or a training effect is confounded.

**Figure 16.** Comparison of HITL Second Lock Times to Soar, TTA, and CTA Base Simulations.

**Figure 17.** The Effect of Presentation Order on HITL RTIC Performance.

**Table 5. Differential Comparison of Second Lock Times.**

The scene density was three for both PVI conditions (all times are relative to the IP).

	Baseline-3 (sec.)	RTIC-3 (sec.)	Difference (sec.)	Error (%)
HITL	44.7	26.92	17.78	
SOAR	55.73	22.25	33.48	88
TTA	61.94	35.19	26.75	50
CTA	55.57	40.81	14.76	-17

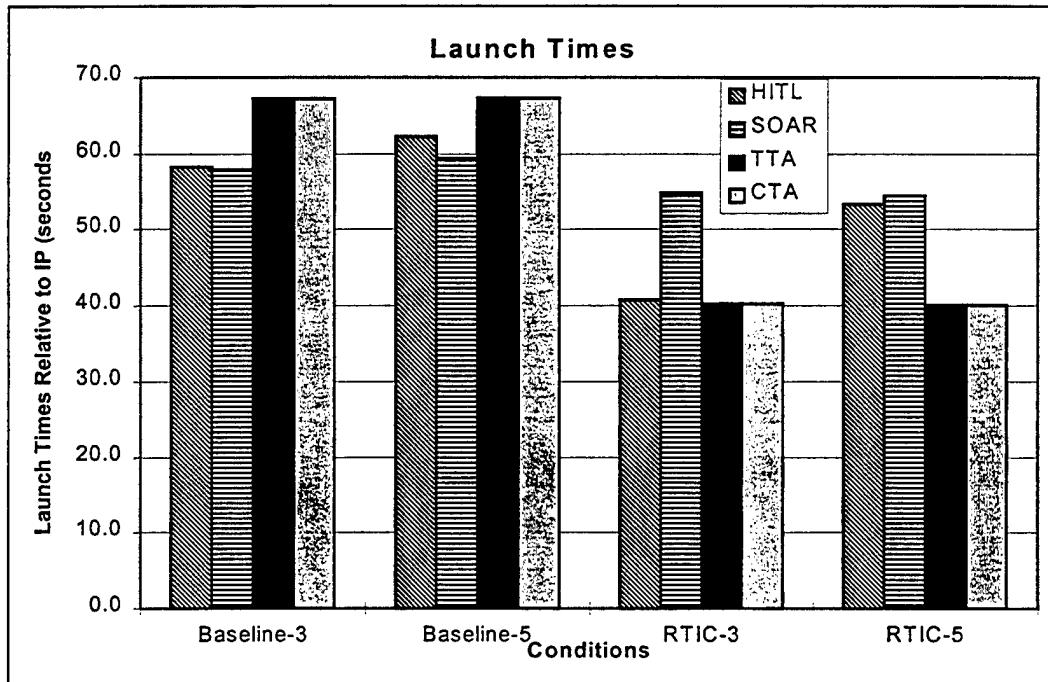

The second lock times also reveal a cognitive effect in the comparison of increased scene complexity. In the baseline condition with three vehicles, on average, the pilot will have to identify two aircraft before finding the KC-10. In the baseline condition with five aircraft, on average the pilot will have to identify three aircraft before finding the KC-10. Thus, in the baseline condition, typically the pilot only needs to focus upon one additional vehicle, whereas the RTIC condition requires focusing on two additional aircraft when the scene complexity is increased from three to five. Hence, scene complexity is expected to increase second lock times for the RTIC condition in comparison to the baseline condition. As seen in Table 6, both HITL data and Soar simulation data have increased scene complexity differences for the RTIC condition as compared to baseline. However, the TTA and CTA models poorly simulate the RTIC scene complexity differences.

**Table 6. Scene Complexity Average Differences for Second Lock Times.**

Model	Baseline (sec.)	RTIC (sec.)	Change (%)
HITL	4.67	13.01	179
SOAR	1.57	2.3	47
TTA	0.42	-0.02	-105
CTA	0.42	-0.10	-124

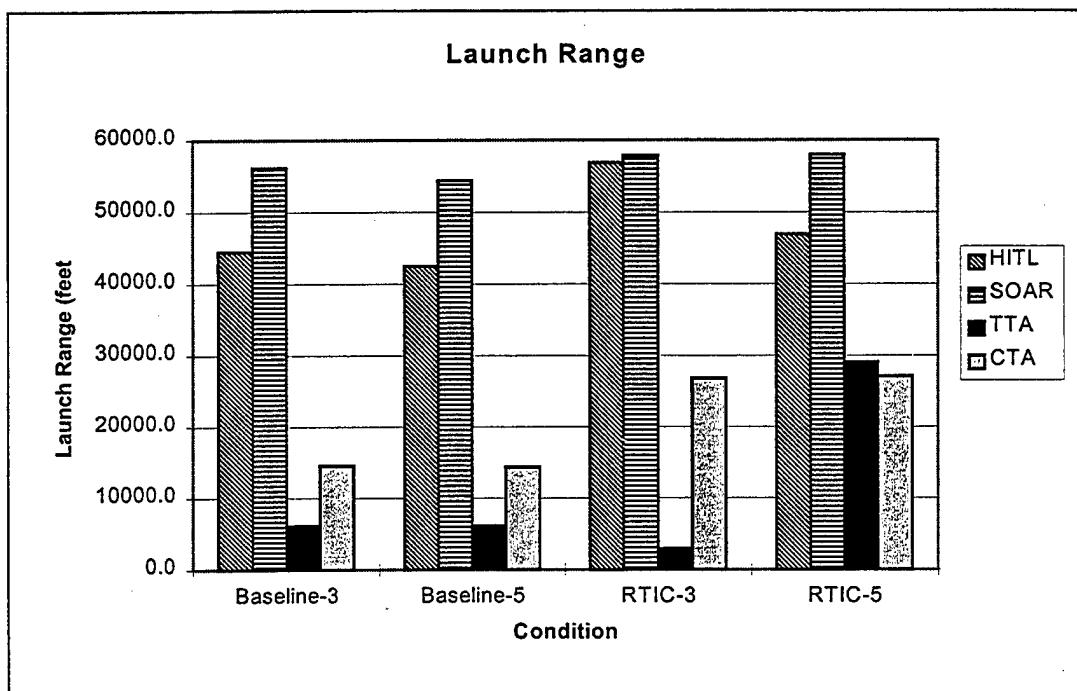

Analysis of launch time differences between conditions is difficult. In the baseline conditions, the HITL and Soar data are very similar. This increased similarity over second lock time is attributed to an apparently hyper motor model of the Soar simulation. What is lost in the Soar simulation is a difference between PVI conditions. This is because the Soar model used a maximum launch range of 58,000 feet. Since the baseline behaviors were near completion at this point and RTIC behaviors always waited to pass this threshold, the benefits of the RTIC behaviors are not identifiable for this measurement. Conversely, HITL data show decreased RTIC launch times because that data did not appear to have a maximum Maverick launch range (one pilot launched from 76,650 feet).

Analysis of launch range is similar to launch time except the TTA and CTA data are problematic. As seen in Figures 18 and 19, it is unknown how launch times for HITL, TTA, and CTA can be so similar, but launch ranges can be drastically different.

**Figure 18. Comparison of HITL Launch Times to Soar, TTA, and CTA Based Simulations.**

NOTE: The better results are the launch times with the lower values because these launches occur closer to the IP point and, therefore, further from the target area.

**Figure 19. Comparison of HITL Launch Ranges to Soar, TTA, and CTA Based Simulations.**

Table 7 shows the number of false alarms increased in the baseline condition as scene complexity increased for HITL, Soar, and TTA simulations. However, the number of misses decreased as scene complexity increased. The explanation is that as the number of distracters increase, the number of false alarms will increase, but the number of targets remained constant so the number of misses should be constant. However, the experimental procedure was to ignore the remaining vehicles once a target was identified. Hence, the increase in false alarms will decrease the number of opportunities to classify the KC-10s and thus decrease both the opportunity for and number of misses.

**Table 7. Performance Measurements.**

HITL responses are compared to Soar, TTA, and CTA simulation responses.

Condition	Number of False Alarms				Number of misses				Number of Trials	
	Baseline		RTIC		Baseline		RTIC			
	3	5	3	5	3	5	3	5		
PITL	3	13	3	8	0	0	0	0	40	
SOAR	6	11	N/A	N/A	7	5	N/A	N/A	60	
TTA	8	28	0	0	4	3	6	10	100	
CTA	0	0	0	0	0	0	14	6	100	

## DISCUSSION

The Soar model of the Maverick strike mission was limited by that mission scenario in that it forced the model to overemphasize the perceptual aspect of human cognitive performance. The model did demonstrate Soar's ability to perform discrete event simulations, but the model did not meaningfully employ Soar's ability to represent the more sophisticated aspects of human cognitive processing. For this reason, this discussion will focus less on the present model's capabilities and look forward to future application of Soar to cognitive modeling. The discussion will first identify classes of events which cognitive models must accurately predict. Second, experiments which utilize the cognitive aspect of the Soar architecture for modeling human cognition, including human limitations and human errors, will be identified. Third, we shall discuss how to compare competing human performance models. Finally, how to compare a cognitive model's predictions with human performance will be discussed.

### Choosing Tasks Suitable for Cognitive Modeling

The Maverick mission biased the model toward the perception process since the task required the pilot to pick a vehicle to strike based on various sensory resources provided in the two cockpit configurations being tested. The mission characteristics drove the model toward a perceptual detection-identification cycle dependent on the range-to-target and the cockpit information display characteristics. The augmented configuration cockpit with overhead imagery eliminated the recognition part of the pilot's

task, making earlier firing decisions possible. The attack ranges were determined by the ability to detect individual targets in the target clusters. Although perception is part of human cognition, it is perhaps the best understood and the least demanding aspect of cognitive modeling. According to the Soar information processing model, perceptual information is fed into short-term memory store where it is processed in combination with long-term memory to enable the human operator to make decisions and take action to accomplish the required goals. The pilot's post-perception cognitive processing for the Maverick mission was trivial (since target vehicle recognition was achieved when enough pixels were available to support pilot perception of the targets) because there were no demanding additional cognitive processes to launching the Maverick missiles.

Tasks suitable for development and testing of cognitive models must exercise most if not all aspects of cognitive processing, including perception, assimilation into short-term memory, consolidation with long-term storage information, decision processes, and the motor response. Thus, choice of the task to be modeled is absolutely critical to developing and testing the modeling process. Test tasks should also permit a variety of alternative operator actions. Particular actions may "mark" the presence of specific cognitive response generation processes. Additionally, post-performance debriefings may reveal more information about the cognitive processes underlying subject action. Thorough test tasks can be developed in two ways: a single full-task which thoroughly tests all aspects of cognition or part-tasks which test specific separate aspects of cognition.

Consider one thorough full-task based on the existing Maverick strike mission that would span all the levels of cognitive processing. This task would require perception of critical information, integrating the new information with existing knowledge, using the combination to make a decision, and the resulting physical response. First, modify scenarios such that high value targets (KC-10s) are not present at every attack; hence, the pilot needs to decide whether to break-off the attack. This would modify the detect-recognize loop to include a decision whether or not to fire. The scenario can be further elaborated by locating the target not just among war planes where an error has little consequence, but civilian transports that may or may not contain passengers. Now

the detect-recognize-decision loop requires greater perceptual precision (capture of more details about the aircraft), additional information from long term storage (a wider range of aircraft types), and the fire decision must consider collateral damage.

The part-task alternative approach would consist of a series of unrelated tasks, each testing a different aspect of cognition process separately. This approach allows dissection of the cognitive process, but sacrifices the opportunity to study complex interactions among the levels. In this fashion, the Maverick mission which tests perceptual modeling would be augmented with events that would separately test other aspects of cognition. During egress from the target area a pop-up threat may appear that requires a decision about how to avoid it. A system emergency may occur which requires weapon system knowledge and integration of prior knowledge.

Multiple decisions are another way in which the cognitive complexity of the modeling test task can be increased. When operators must trade-off outcomes in two or more processes, as often is the case in real life tasks, the cognitive model can be tested under more realistic circumstances. This can be illustrated in our Maverick mission by the addition of terminal defenses in the target area. The original mission had the pilot fly unopposed into the target area. The presence of terminal defenses would add increasing risk with greater proximity to the targets. The range of this risk would depend on the aircraft threat warning system, pilot understanding of threat characteristics and mission priority. Parallel processing of the threat problem further complicates the cognitive processing demands on the pilot or model and puts greater load in the latter stages (information, integration and decision) of the cognitive process.

If cognitive modeling intends to predict human operator performance, models must respond to environmental stressors like their human counterparts. Models must be able to incorporate the effects of temporal pacing, effort, environmental stress (temperature, g-load, etc.), and fatigue. Combat environments are very different from the laboratory conditions, so that generalization is sometimes unjustified. Creating realistic models will require collecting data under as realistic conditions as possible.

### Enhancing Soar's Similarity to Human Cognition

Newell (1987) intended Soar to perform cognition in a way similar to that of human cognition. However, the existing Soar architecture only partially achieves this goal. Although, in principle--Soar functions in a human-like fashion, its computational representations of working and long-term memory are far more powerful than their human counterparts. Soar's departures from human cognition are well understood. Working memory is meant to function like short-term memory, but working memory has unlimited capacity while human short-term memory has considerably less capacity (Miller, 1957). Soar's knowledge base is permanent, monolithic, and represented as rules and their firing conditions belying its artificial intelligence production system origins. Human knowledge is much more complex, marked by imperfect retrieval, representations varying over time, interactions with sensory modalities, and configured into non-uniform schemata (Neisser, 1976). Soar must be further anthropomorphized for it to accurately model human cognitive performance.

Dr. Laird at University of Michigan (personal communication), a project consultant, has identified several ways that the Soar architecture can be exploited to make its information processing more anthropomorphic. The changes Laird suggests do not alter Soar's basic function. The changes modify the contents of working memory or change rule processing to mimic known human processing characteristics.

The first proposed change is meant to mimic high stress or workload conditions. Human error rates increase under such conditions while unmodified Soar processing is unaffected. The change involves the withdrawal of rules from working memory to mimic changes in short-term memory under stress. Those withdrawn rules would not fire and the resulting decisions would not be based on all the available information. A critical issue for withdrawing rules is choosing which to remove. Random withdraw is one way. Another way is to track the frequency of past firings and lose less frequently firing rules first.

Second, Laird proposes limiting the number of productions fired in parallel under stress or workload. This would reduce the throughput of cognitive processing and

make cognition more of a sequential than a parallel process. Human ability to perform dual tasks simultaneously is limited and affected by the nature of the tasks (Wickens, Sandry & Vidulich, 1993).

A third method for anthropomorphizing Soar is to limit the cascades of production firing during the elaboration/decision cycle. The elaboration/decision cycle now considers the consequences of every potential firing on every other firing before making decisions. Human decision makers are typically not as thorough in testing the consequences of each decision and consequently make errors based on the failure to predict the broader consequences of their decisions. Limiting cascades of firings will increase Soar errors, but it remains to be seen whether these errors mimic those made by human operators.

The next two alterations of Soar function deal as much with the supporting computational environment as they do with Soar itself. Laird suggests artificially restricting execution speed, so as to prevent Soar from thoroughly processing the inputs in the available time. Pilots in the HITL simulation had only moments to detect and recognize the strike targets; under less time pressure they probably could have performed better. Soar, running on a fast computer might be able to process more information in the allotted time compared to its human counterpart. The IBM chess program Deep Blue beat a human competitor by thoroughly searching alternative courses of action faster and more accurately than its human opponent.

Another way processing speed can be limited is by adding additional tasks to reduce the processing time available for the cognitive processing. Pilots devote significant mental effort to flying their aircraft, a process that competes with available resources to detect, identify, and strike their targets. This siphoning of cognitive capacity is managed in two different ways in the design of strike aircraft. One design strategy is to include a second crew person dedicated to operating weapons. The F-15E Strike Eagle has a two person crew, one of whom is a dedicated weapon systems officer. The other design strategy is to automate some of the tasks so that a single crew person can perform the whole mission. The F-117 Nighthawk opts for the latter method, automating flying while the pilot concentrates on operating the weapon systems. Loading

the processor with ancillary tasks to reduce Soar processing cycle times mimics the workload issue in humans. Furthermore, Soar's processing speed must be matched to the amount of information a human operator can consider per the available processing time. Either the restriction of execution speed or the addition of competing tasks will require empirical studies to determine how much elaboration cycle time for any given Soar-hardware implementation are comparable to human performance and how elaboration cycle time may vary with training and experience.

The last potential modification to Soar to increase its similarity to human cognition is to vary the design of its knowledge base. The form, organization, and order of the rules with which Soar operates on its perception is central to cognitive processing. Neisser (1976) discusses the role of schemata or the organization of knowledge in the cognitive process. Hutchins (1995) further shows how very different schemata can be employed to support the same behavior, in his case, vessel navigation. In a simple form, novice behaviors can be compared to expert behaviors based on the depth and organization of their knowledge bases. However, more subtle differences in the knowledge base may provide greater understandings of Soar model behavior and ultimately human behavior.

#### Making Comparisons Among Competing Cognitive Models

This was one aspect of the current modeling effort that was very well managed by the Air Force Research Laboratory. Both the HITL and EADSIM data collections preceded development of the Soar model, so our Soar development team was kept blind to the earlier efforts. Only the particulars about the Maverick mission, and the dependent variables used to measure their performance, were provided during model development and testing. The results of the other efforts were made available only after the model data collection was completed.

There was one minor error in the information transfer for preparing the model. We were told that pilots could not release their Maverick before reaching the weapon's maximum range of 57,000 yards. The Soar model was programmed to incorporate this constraint, despite the fact in some conditions the decision to fire was made long before

the aircraft reached that distance from the target. The Soar model was programmed to delay weapons release until reaching the Maverick's maximum range. Unknown to our modeling team, pilots in the HITL simulation often released their missiles before reaching the missile envelope limits. This erroneous behavior is understandable because the decision to fire was made so much earlier in the approach, especially in the enhanced cockpit condition. This oversight produced an artificially induced discrepancy in weapon release range between the Soar model and the HITL simulation results. Clearly, equivalent behaviors were thwarted by not enforcing the Maverick missile release envelope during the HITL simulation.

The simplicity of the Maverick mission did not afford opportunity to explore comparative measures between models or error analysis. Multiple model runs can be used to determine probabilities of specific errors that could be compared across competing models. The types and conditions under which errors occur are a substantial basis for judging model fidelity. Error analysis could be further expanded, at least in Soar, to look at the antecedent conditions to committing the error. Soar can record the operations of its elaboration/decision cycle so that runs resulting in errors can be dissected to determine why the errors occurred.

#### Comparison of Cognitive Models to Human Performance

The true potential utility of cognitive modeling comes in its comparison to human performance. Early comparisons will largely be made to tune the fidelity of Soar based models and other modeling methods. Most of these comparisons will be like the ones described above between different cognitive models. Comparative dependent measures will be identified and the differences between model and human performance will be made much as it has been done here for the Maverick mission. Once the models have been tuned to mimic their human counterparts, cognitive models will be ready to serve as the first significant tools for cognitive engineering.

Engineering involves the systematic application of codified knowledge to permit design of systems with confidence in the ultimate performance. What has previously passed as cognitive engineering has been nothing more than artful application of cog-

nitive science to the system design process. Cognitive information has not been codified sufficiently to allow its application in a systematic fashion. Thus, cognitively derived designs lack our confidence and sometimes do not out perform traditional designs. Cognitive models may codify our knowledge in such a way to allow reliable prediction about a proposed design's ultimate performance.

Perhaps the most important use of cognitive models in the engineering process will be the discovery of design-based errors made by operators. Cognitive models can be used to conduct large numbers of mission simulations under wider ranges of conditions than are feasible with HITL simulations. Environmental stressors (like fatigue, temperature, terrain, weather), unusual events, and all combinations of system failures could be simulated sufficient numbers of times to identify and establish probabilities of errors as well as capture the rare combinations of events leading up to catastrophic failures. Furthermore, Soar models can provide the diagnostic information about how the cognitive events precipitate error. These failures could be verified by programming their antecedent events into HITL simulations to validate the cognitive modeling results. These kinds of error analyses could be powerful predictive tools for cognitive engineers, enabling virtual test of system interface designs before they are actually implemented. Cognitive models hold the potential to put the engineering into cognitive engineering.

## RECOMMENDATIONS

The present modeling effort establishes that Soar can model the same kinds of tasks that discrete event models can, and with an enhanced perceptual representation perform as well or better than discrete event simulations like EADSIM. The particular mission given to be modeled did not exercise Soar's cognitive modeling capabilities beyond the perceptual capabilities. The principle recommendation is that Soar should be applied to more cognitively demanding tasks, either tasks that span multiple features of cognitive processing or suites of tasks that focus on particular aspects of cognitive processing.

Perhaps the best way to approach creating a comprehensive cognitive model is to model "slices" of cognitive behavior (the part-task approach) which are constrained

by limited input, outputs, and event complexity. Such limited models could serve as test beds where the effects of the anthropomorphizing modifications could be tested and compared with similarly constrained, HITL simulations. These limited scope models should be designed so that they could be linked either in serial or later in parallel so that interactions in their operations can be compared to their earlier function in isolation. In this fashion, a more comprehensive model of operator function could be built while exploring the basic science issues of modeling human cognition.

Model elaboration would eventually produce a comprehensive model of a human operator that could be tested in a fashion suitable for cognitive engineering predictions of performance. More complex event scripts and more cognitive demanding events could be introduced so that the error analysis discussed earlier could be performed. In this way, definitive predictions could be made about where human errors can be anticipated and the antecedent events could be used to prepare HITL simulations to discover the hypothesized error points. Data could also be recovered from devices like flight recorders or from accident investigations to determine whether the predicted errors are encountered in real systems. The ultimate goal of such efforts would be to create an engineering procedure by which operator stations can be thoroughly modeled and tested so that cognitive engineering becomes less of an art and more of an engineering science.

## **APPENDICES**

- 1.1 Final Data
- 1.2 Complete Set of Pixelated Views of KC-10 and B-52
- 1.3 Selected Text Output from Baseline Condition
- 1.4 Selected Text Output from the RTIC Condition
- 1.5 Snapshot of Plane Firing on Targets
- 1.6 ANOVA Results
- 1.7 Soar Code

**Appendix 1.2**  
**Complete Set of Pixelated Views of KC-10 and B-52**

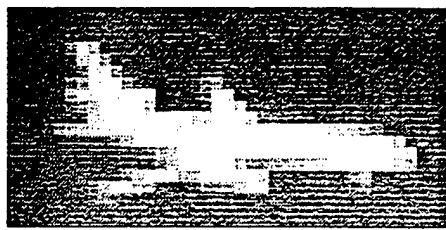

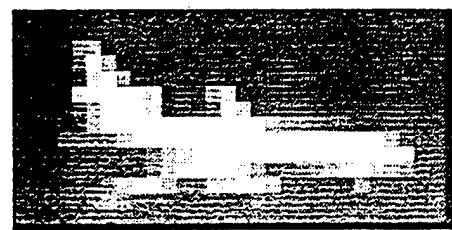

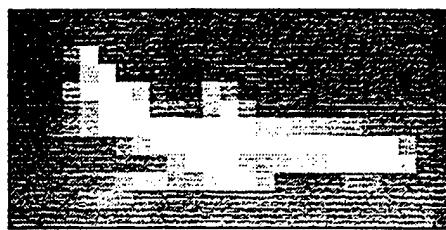

Different levels of pixelation of a KC-10 Model at an orientation of 0 degrees.

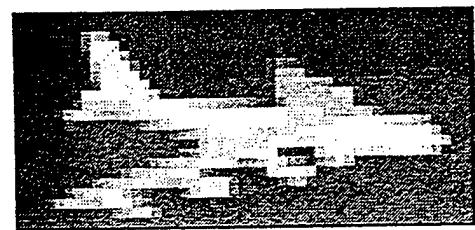

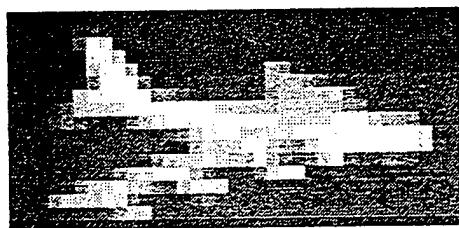

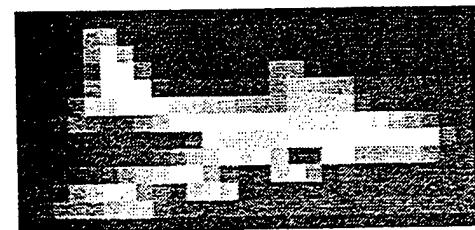

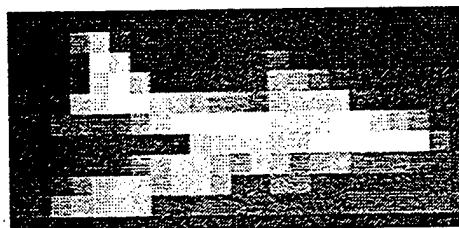

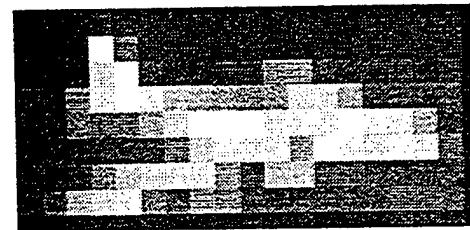

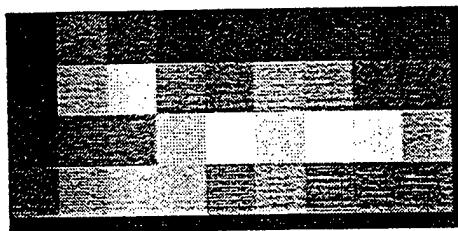

Different levels of pixelation of a B-52 Model at an orientation of 0 degrees.

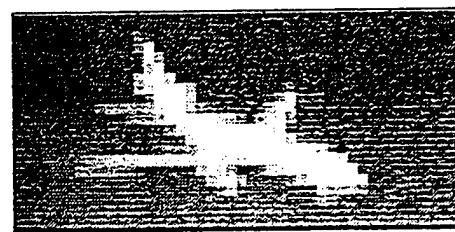

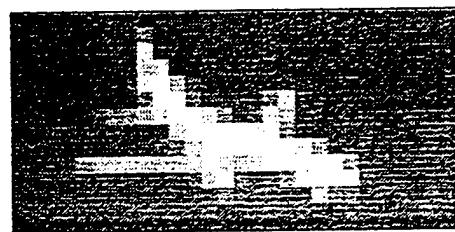

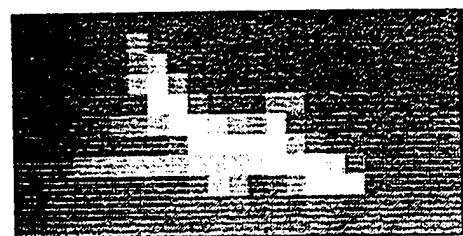

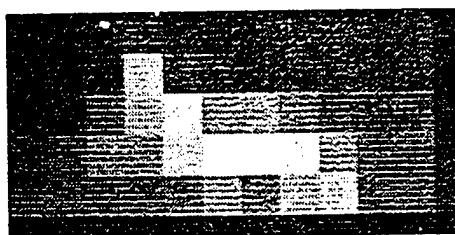

Different levels of pixelation of a KC-10 Model at an orientation of 30 degrees.

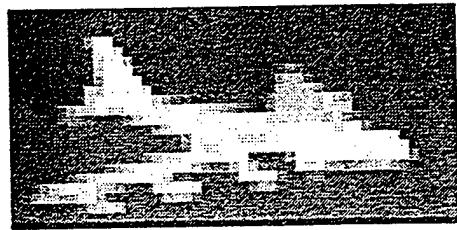

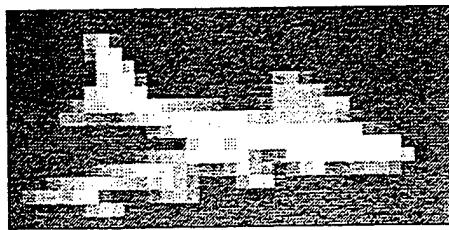

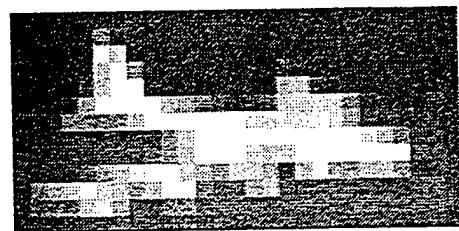

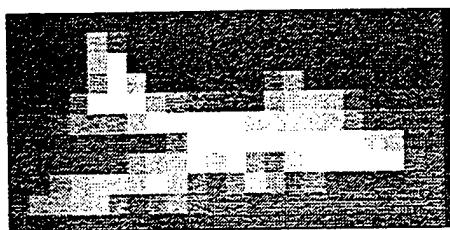

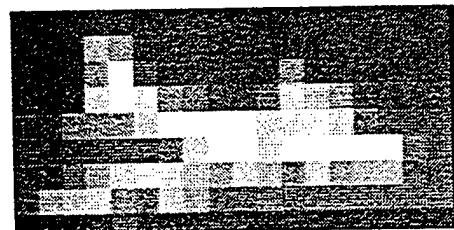

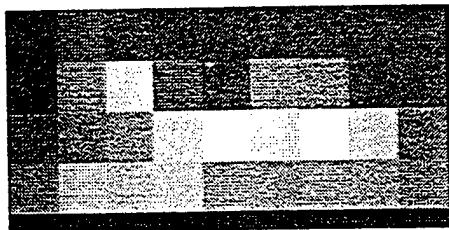

Different levels of pixelation of a B-52 Model at an orientation of 30 degrees.

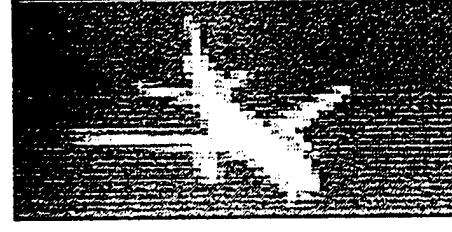

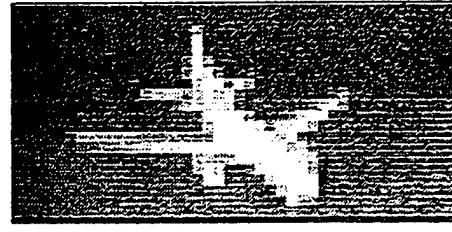

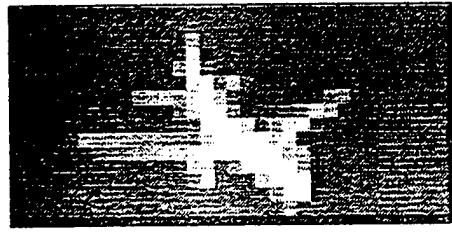

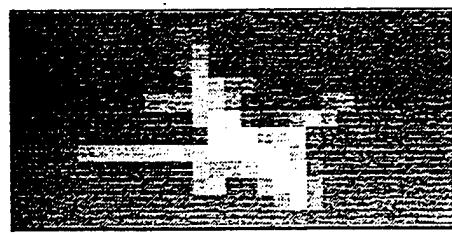

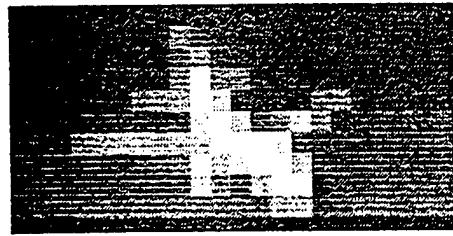

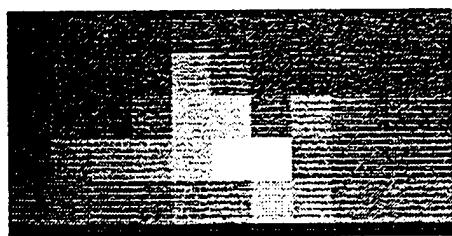

Different levels of pixelation of a KC-10 Model at an orientation of 45 degrees.

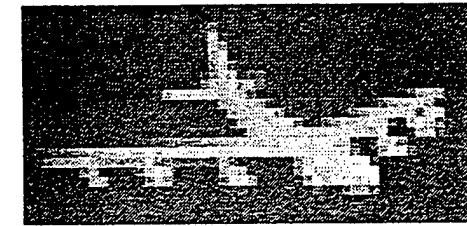

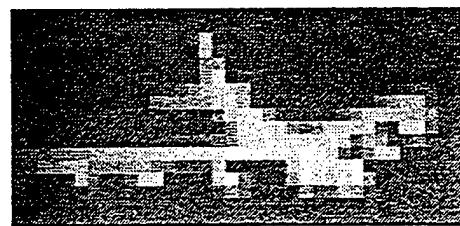

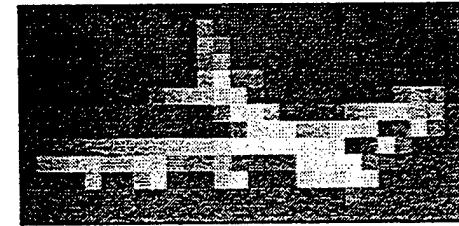

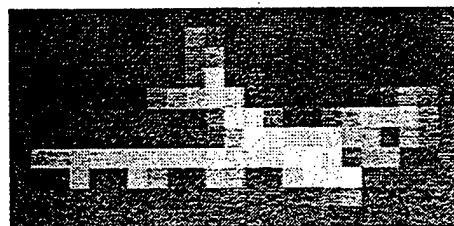

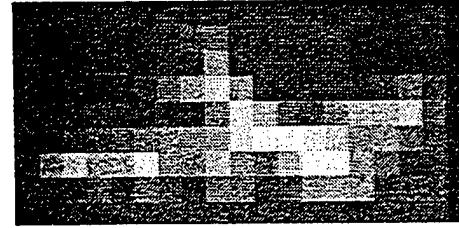

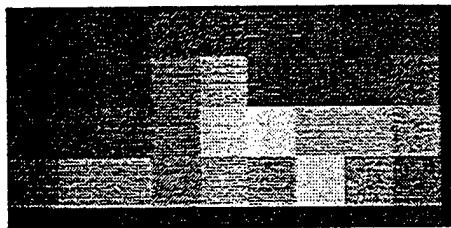

Different levels of pixelation of a B-52 Model at an orientation of 45 degrees.

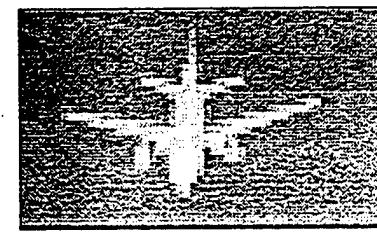

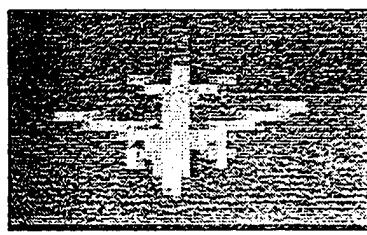

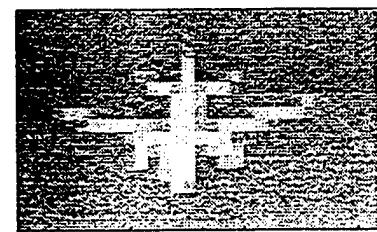

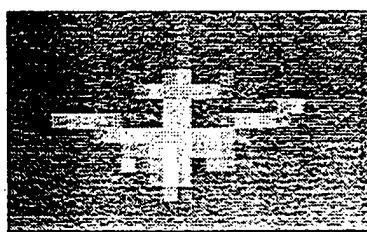

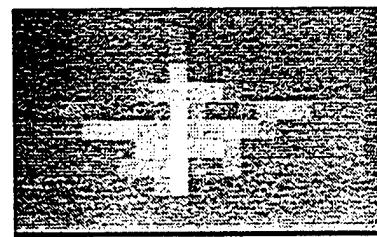

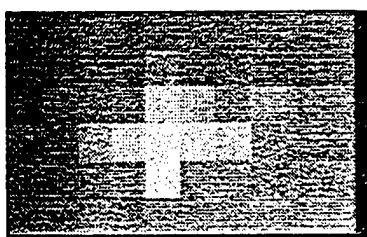

Different levels of pixelation of a KC-10 Model at an orientation of 60 degrees.

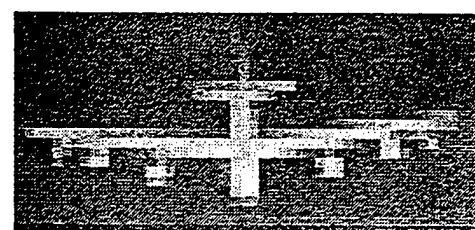

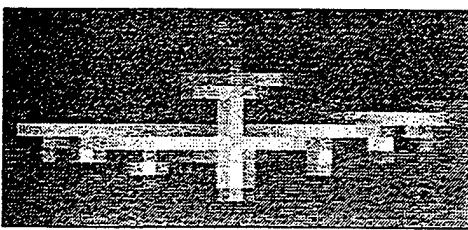

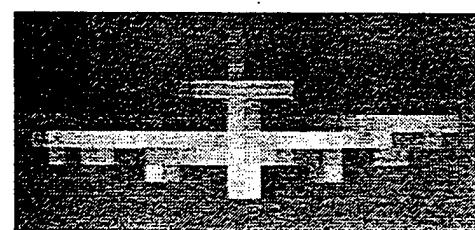

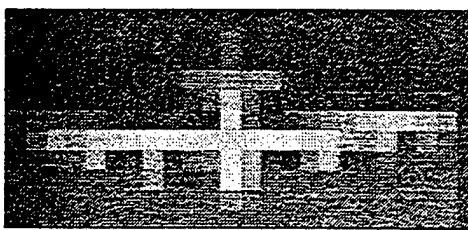

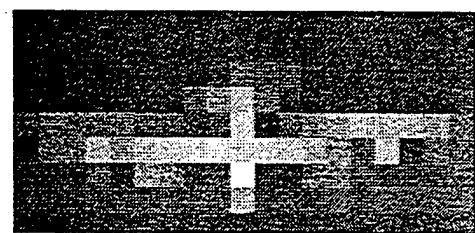

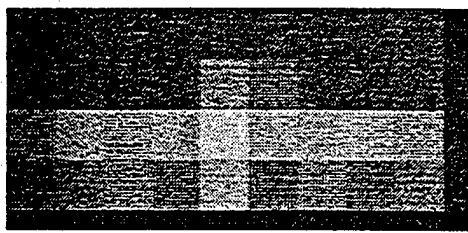

Different levels of pixelation of a B-52 Model at an orientation of 60 degrees.

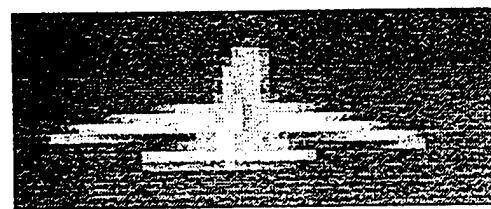

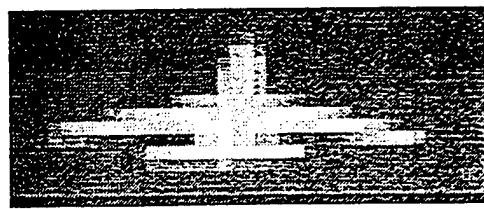

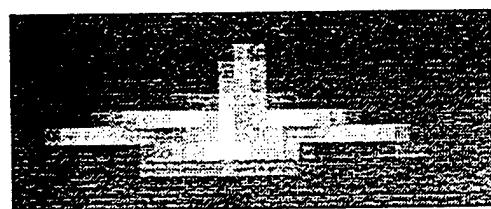

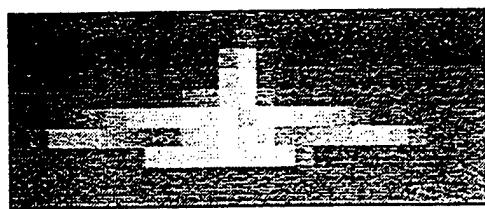

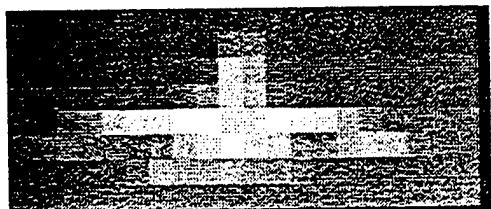

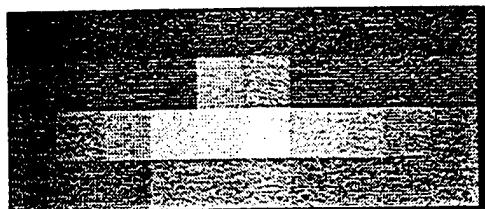

Different levels of pixelation of a KC-10 Model at an orientation of 90 degrees.

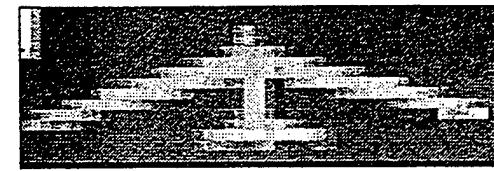

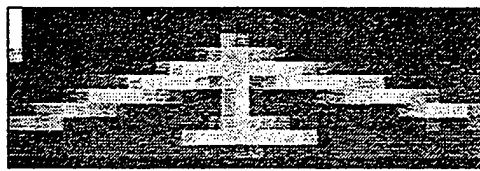

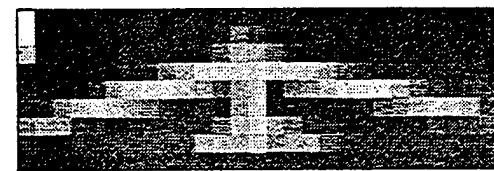

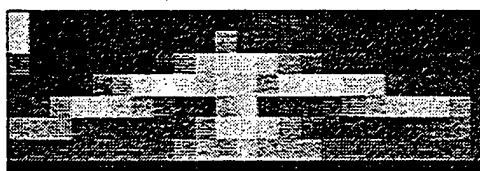

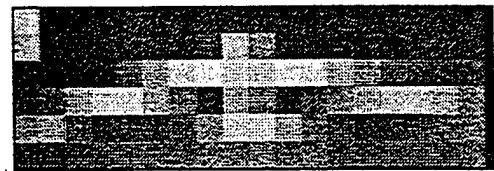

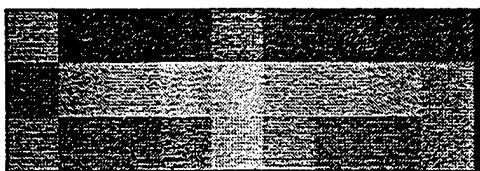

Different levels of pixelation of a B-52 Model at an orientation of 90 degrees.

Different levels of pixelation of a KC-10 Model at an orientation of -90 degrees.

Different levels of pixelation of a B-52 Model at an orientation of -90 degrees.
